Treatment is in theory simple for the worms are easily destroyed by a number of drugs such as gentian violet thymol or one of the proprietary remedies. Ointment is applied to the itching area and the child should be prevented from scratching. However since the eggs may lie about the house for some time reinfection often happens especially if there are several small children in the home who may pass the disease from one to another.

The idea that intestinal worms in general are likely to cause loss of weight by absorbing food eaten by the patient is largely mistaken for although it is true that they do live on this food the amount taken is certainly not enough to be significant.

Tropical Worms Bilharzia has been mentioned before in connection with its frequency in Egypt although it is also found in other parts of Africa Arabia and Iraq. There are two main types one infecting the bladder (*schistosomum haematobium*) the other the rectum (*schistosomum mansoni*). Bilharzia is more correctly known as schistosomiasis.

The parasites fantastic life history begins when a man bathes in infected water and the small swimming forms known as cercariae pierce and enter his skin—or they may enter the body by drinking infected water. From the skin they pass to the portal vein below the liver remain there six weeks until they become adult and then swim against the blood stream down to the pelvis where the female lays eggs which have a sharp spine. The eggs penetrate into the bladder or rectum—depending on the type of fluke—and pass out in the faeces or urine. If they enter water they hatch out into small moving forms which seek out a water snail develop further in its body and leave it in the form of cercariae ready to find a new human victim. The female fluke is slender and round about 1 in in length the male flat and leaf shaped is about $\frac{1}{2}$ in long and as we have seen their grisly courting takes place in the portal vein whence the unpregnated female

passes to the bladder (hæmatobium) or rectum (mansoni) to lay her eggs

Infection results in raised temperature and in the urinary type blood in the urine in the intestinal type blood is found in the faeces and there are symptoms resembling dysentery—*e.g.* diarrhoea. Treatment in both cases is by injections of antimony tartrate. Needles to say attempts should be made at prevention by telling people to avoid infected canals (usually easier said than done) and by periodically cutting off the water supply to the canals to kill the snails

Hookworm Disease or ankylostomiasis is found in many parts of the world especially in miners who work on damp ground. The tiny worm enters the body usually through the feet passes through the blood stream to the lungs eats through into one of the bronchial tubes climbs the windpipe and passes down the oesophagus into the stomach to end up in the quodenum. It causes anaemia can be fairly readily cured but is occasionally fatal

Elephantiasis Some types of parasitic worm are spread by insects. Thus in *Filaria* mosquitoes inject by their bites the infantile forms of a tiny worm which enters the lymphatic channels there the blockade they cause leads to the swelling of the legs and the lower part of the body known as elephantiasis

PHYSICAL INJURIES

INTRODUCTION

In this section we shall inevitably discuss much that could be described as Principles of First Aid. You cannot learn First Aid from a book even if you read one of the excellent first aid manuals like those published by the St. John Ambulance Association. The only way is to join one of their many classes of practical and theoretical instruction which are held in all parts of this country and many others. There is much to be said for many more people receiving instruction to judge by the level of general ignorance and ineffectiveness to be witnessed at most road accidents before the ambulance comes

The most difficult thing to learn is what *not* to do. When a patient is knocked down in the road people instinctively seem to want to drag him immediately to his feet or otherwise pull him on to the pavement away from the traffic. Someone will have entered the nearest shop and be emerging with a chair so that the casualty can sit down. Before long a hot strong sweet cup of tea has arrived and thus or some other beverage is being poured into him. All this is instinctive and all of it is wrong. Do *not* move the patient until you are sure he has no fracture which will be further aggravated by movement. To take an extreme case a fractured spine clumsily moved may result in permanent widespread paralysis. Guard your patient from the traffic but only move him when you are certain it is safe to do so. If he has any injury which is likely to require a general anaesthetic on arrival in hospital (and this applies to most fractures) do not give anything at all by mouth. No anaesthetic can be given to a patient who has eaten or drunk anything in the previous three hours in case he vomits while unconscious and dies of obstruction of his airway. Keep your patient warm (do *not* warm him up artificially) keep his head low and unless he is bleeding severely or has stopped breathing do nothing but protect him from the ministrations of the uninstructed until the ambulance comes

Injuries to the Head and Back.

The head contains the brain an organ with a number of inconvenient properties from the point of view of injury. Its very great importance is matched by its very great vulnerability as a tissue. Its consistency is that of stiff junket. It is quite incapable of repair once damaged and cannot heal by growing new parts in the way that skin

and bone can. So it has to be totally enclosed by protective bone which means it cannot swell without compressing itself dangerously within its box—and this not infrequently happens after injury. Furthermore any bleeding into the interior of the skull can only occur at the expense of compressing the brain since the brain box is already fully occupied by the brain. There is a story in first aid known as Concussion and Compression. It begins with a knock out blow to the head and this is known as concussion. The patient's skull a hard enough blow to the head will lose consciousness if only for a short time due to the brain being shaken up. Even slight knocks would do this if the brain were not cushioned by a thin layer of cerebrospinal fluid. Most concussed patients quickly regain consciousness and for the great majority that is the end of the affair except for a sore head and a headache for a few days. Unfortunately a minority even though there may have been no fracture the blow that knocked them out will also have damaged a small blood vessel on the surface of the brain. These patients may be indistinguishable from the luckier ones at first. They may have regained consciousness and will be just as anxious to go home. They will often be quite lucid for some hours. Surgeons call this the lucid interval. However when more than a certain amount of blood has accumulated in the head and the brain is sufficiently compressed by it the patient loses consciousness slowly for a second time and from this phase of compression he will not recover unless something is done. The lucid interval can last some hours. Brain surgeons can relieve the compression and save the life of the patient only if they have him in their care when it occurs. This is why a 'cases of head injury who have once lost consciousness (concussion) for however short a period of time and however lucid they may subsequently appear all must be seen by a doctor and if thought necessary observed overnight in hospital in case they are bleeding and proceeding to compression. There is no way of saving these avoidable fatalities other than by treating all cases of concussion seriously. Fractured skull is potentially even more serious because the blow will have been harder and the brain is therefore more seriously at risk

The spinal cord can be regarded as an extension of the brain which runs down the middle of the spinal bones of the vertebral column. It has the same delicate consistency and the same inability to recover from injury as the brain. Injury is usually the result of a fracture dislocation of the spine. The consequences of injury are due to a permanent interruption of its two main functions. All movements of the voluntary muscles are only possible if they are connected by nerves to the brain. Except for muscles in the head all these motor nerves run in the spinal cord. The nerve pathways leave the skull through a large hole in its base and run down in the spinal cord to the required level. They then emerge between the spinal bones and travel in bundles to reach the muscles. Motor nerves for the arm leave the cord between the vertebrae of the neck. Those for the leg leave the cord in the lumbar region in the small of the back. If the nerve supply is damaged in any part of its course, the muscles being supplied become paralysed and are unable to move. It follows that if the spinal cord is damaged all muscles below the point of damage have been cut off from the brain and will be paralysed and this will be permanent because the cord cannot be repaired. Damage to the nerve pathway after it has left the cord can often be repaired. Permanent paralysis is only one of the consequences of cord damage since there is another whole series of nerves running in the cord which carry sensations from all parts of the body to the brain. Therefore there will be loss of sensation as well as paralysis below the point of injury

It is emphasised that fracture of the spinal bones can occur without damage to the cord taking place. It is when these bones move one over the other or dislocate, that permanent cord damage occurs. It is therefore extremely important that cases of back injury be moved

very carefully indeed in order to avoid such a disaster and special ways of moving such patients are taught in First Aid classes

Haemorrhage and Shock.

Every part of the body must have a blood supply or else it will die. It is possible to stop the blood supply to a leg for example by fastening a wide rubber bandage tightly around the top of the thigh. This so called constrictive bandage is still mentioned in First Aid books as a desperate means of controlling haemorrhage in a limb. It should hardly ever be used because by stopping all circulation of blood the entire limb will die in the course of time. Besides most haemorrhage can be stemmed by direct pressure on the bleeding point. The tissues of the leg such as its muscle and skin and bone will begin to die in a little more than half an hour after cutting off the blood supply. The brain however will begin to suffer within three seconds of its blood supply being cut off and will die in about three minutes. Thus it can be seen that some parts of the body are more susceptible than others to a failure of the blood supply and the brain suffers earliest of all. Since the brain is where most of the vital functions of the body are controlled it follows that a shortage of blood to the brain is likely to lead to a depression of the vital functions—a state of affairs known to First Aiders as shock.

Shock occurs in a number of conditions but is always due to a failure of the supply of blood to the vital functions of the brain for one reason or another. Its usual causes are

- (1) haemorrhage when there is a general shortage but the brain feels it most
- (2) severe burns in which much fluid is lost from the blood as will be seen later and
- (3) certain medical conditions causing acute heart failure in which there is a failure to pump blood to the brain because the pump has failed

The treatment for shock consists basically of restoring the blood supply to the brain and where it is caused by loss of blood or other fluid the treatment is transfusion. Finally it must be emphasised that treatment is always urgent since the brain cannot function for long without its blood supply and once damaged by the shortage can never be repaired. No attempt is made here to describe such treatment completely but the most important things are to keep the head low so as to reduce the work the heart must do to drive blood to the brain and to avoid artificial heating of the body by hot water bottles etc. which only diverts blood away from the brain where it is needed into the skin where it is not.

The treatment of severe haemorrhage is to stop the bleeding usually by firm direct pressure and then to remember above all things that even though the bleeding has stopped there may be a dangerous state of shock from which the patient could die. This can only be prevented by restoring the circulation to the brain usually by transfusion so having stopped the bleeding drive him fast to hospital for the second part of the treatment which may be as necessary to save his life as the first.

There is great confusion over the use of the word shock. In the lay mind it is a shake up of the nervous system caused by a fright or some bad news or the sight of something nasty in the woodshed. Even in the medical mind it is some times confused and some of the First Aid books confuse it still further. Too frequently they give the treatment as loosen all tight clothing from neck chest and waist reassure the casualty and ensure a good supply of air. All this together with grandmothers hot strong sweet tea is perfectly good enough if the patient is only shaken up by a fright or a fall but it will be dangerously negligent and time wasting if he is suffering from true shock due to a failure of blood supply to the brain.

Fainting is a special case which can be prevented by keeping the head low in those who feel faint. It is usually self curing due to the patient automatically falling into a position in which the head is low. If the faint however is due to severe blood loss this is the same as shock in our proper meaning of the word and must be treated accordingly.

Haemorrhage can therefore be a difficult problem. It is even more so when it is internal. This may be in medical crees such as in occasional cases of peptic ulceration in which the blood will be vomited and also passed in the stool. Or it may be surgical in the sense of being caused by injury to internal organs. The blood may emerge from one or other of the various orifices of the body or it may be entirely concealed within the body. Rupture of internal abdominal organs such as the spleen kidney and liver can occur with surprisingly little to show in the way of external injury. A fractured thigh bone can pierce the main artery of the leg and cause lethal internal haemorrhage without a drop of blood being visible. In all these cases diagnosis is urgent followed by emergency blood transfusion if the brain and hence the patient's life is to be saved.

Means of detecting the presence of severe haemorrhage without seeing any blood are taught in First Aid Classes as the Signs of Haemorrhage. They are in fact manifestations of the reactions of the body in its attempts to save the failing brain and are therefore the same as the signs of shock. The main ones are a rapid feeble pulse getting more rapid and more feeble as time goes on in a desperate attempt to get the remaining blood to the brain skin pallor caused by constriction of blood vessels near the surface so that the blood which remains is shunted to the brain away from the less vulnerable skin and finally just before death restlessness and air hunger.

A word of warning about the First Aid treatment of shock due to heart attack (coronary thrombosis). These patients must be transported at complete rest but many of them react very badly to being made to lie down since they have great difficulty in breathing in this position. Transport them relaxed in a sitting position supported by a large comfortable back rest.

It cannot be too strongly emphasised that with haemorrhage and shock as with so many First Aid emergencies the importance of protecting the brain is paramount.

Asphyxia

The previous section was concerned with maintaining an adequate supply of blood to the brain. This is needed in order to supply the brain's only possible fuel—glucose—and the oxygen with which to burn it. Many different circumstances can conspire to reduce the oxygen content of the blood and the result in each case is asphyxia. Normally air is taken into the lungs through the air passages and brought into contact with all the circulating blood. It diffuses from the lungs into the blood where it enters into a special relationship with the pigment of the red cells—haemoglobin. At the same time the waste gas carbon dioxide enters the lungs from the blood and is breathed out. The revitalised blood is passed through the heart to build up sufficient pressure to drive it into all the tissues of the body and in particular into the brain. A special system in the brain—the respiratory centre—controls the complicated machinery of respiration and is itself of course kept alive by the products of the very mechanism it controls. This mechanism consists of all the muscles of respiration—those which lift the ribs the diaphragm and many other so called accessory muscles. They all have to be finely co-ordinated by means of nerve impulses which begin in the brain pass down the spinal cord and out to the muscles. Information of many kinds comes along sensory nerve pathways to the respiratory centre so that breathing can be automatically adjusted to the changing needs

of the moment In order that life may continue there must be

- (1) a functioning breathing mechanism to revitalise the blood and
- (2) a circulation to carry the revitalised blood to the brain and other tissues

In many cases when breathing stops and unconsciousness supervenes as brain function is depressed the heart will go on beating for some time longer. The aim of First Aid is to restore the breathing by artificial respiration *before the heart stops*. Once the heart stops—and it eventually does so abruptly and without warning—the brain is dead within the usual few minutes unless *both* the heart and the breathing are restarted, and this is a very much more difficult proposition than artificial respiration alone.

For these reasons a patient whose breathing has stopped must have it started again without any delay. Here as in the case of severe haemorrhage it is no use telephoning the doctor or even putting the patient in an ambulance. The First Aider must act himself because he is on the spot and the only one in a position to save life. Both actions require elementary First Aid training, and even school children can accomplish them if they have been well taught.

Asphyxia is the name given to a failure of the oxygen supply to the brain and is due to a break down in some part of the complicated breathing mechanism outlined above. One of its chief causes is a blockage of the airway by (a) solids or (b) liquids. Any foreign body of the right shape and size will block the airway as also will the tongue in the unconscious patient. Remember how much more easily the child's airway can become blocked because it is so much smaller. Blockage by a liquid is of course drowning. Remember that if a patient drowns in the entire ocean it is only about half a cupful which is doing him any harm—as it only takes this amount to fill the airway. The same goes for the amount of tea or vomit required to kill an unconscious patient if it gets down the wrong way—as it will unless someone prevents it.

Another very common cause of asphyxia is carbon monoxide poisoning. Carbon monoxide is a lethal component of car exhaust fumes in completely burning and badly ventilated fires and stoves and domestic coal gas. One of the inconvenient properties of haemoglobin is that it combines with carbon monoxide very much more eagerly than with oxygen. Prolonged contact with even a very slightly contaminated atmosphere can build up a concentration of carbon monoxide in the blood which will prevent the blood from carrying sufficient oxygen—and this is in fact how it kills. It takes a very short time for this to happen if the atmosphere is heavily contaminated. Remember the danger of even a very slight leak of the gas either in the kitchen or into a car from a faulty exhaust pipe or silencer. Many elderly people die of coal gas poisoning every day because their sense of smell is poor and they do not detect the leak.

Other causes of asphyxia are lack of oxygen in the atmosphere as occurs at high altitudes, crushing of the chest so that the ribs cannot move, paralysis of the muscles of breathing by interference with their nerve supply usually in First Aid as a result of a broken neck and consequent damage to the spinal cord (poliomyelitis can occasionally produce the same effect by attacking the nerves just before they leave the spine) and depressing the respiratory centre in the brain most commonly nowadays by barbiturate poisoning.

The only really effective method of artificial respiration which all members of any civilised community should be able to carry out can be learned in half an hour at a good First Aid class. This is the direct mouth-to-mouth method sometimes dramatised by journalists as the 'kiss of life'. The method is taught with the aid of models and cannot be satisfactorily learned by only reading about it.

In discussing asphyxia we have again had to consider the particularly vulnerable situation of the brain.

Fractures

Broken bones are not the most serious possible consequences of injuries causing fractures. It is usually more to be feared that further damage will be done by the broken ends of the bones to tissues and organs in the neighbourhood of the fracture. The First Aid treatment of immobilising the part before transporting the casualty is designed to avoid this.

Six types of fracture are commonly taught but some of them may co-exist in the same injury and the division is only for descriptive purposes. In addition there are two special fractures of the skull.

A simple or closed fracture is where only the bone is broken without damage to surrounding tissues and without a wound. A compound or open fracture is one in which air and hence germs can get at the broken bone. This may be through a wound in whose depths lies the broken bone, or the bone may have been pushed out through the skin or a bullet track may lead down to the fracture. All these are examples of compound fracture and the great danger is that the bone will become infected. Even now that infections are less feared than before the days of antibiotics it is still a grave matter for bone to get infected. However the antibiotic is given we rely on the blood supply to carry it into the infected tissue and bone has only a very small blood supply. If the infection is not successfully treated it can smoulder for a long time and become a chronic osteomyelitis which might ultimately necessitate amputation of the limb—and all because the original fracture was compound or open.

A complicated fracture is one in which the broken ends of the bone have damaged some important organ or tissue in the region. For example a complicated fracture of the ribs is one in which the lung tissue close behind the inner surface of the rib has been pierced, and the patient will be coughing up small amounts of bright red frothy blood. A comminuted fracture is one where the bone is broken into several pieces and an impacted fracture is one in which the broken ends have been driven into each other and are firmly impacted. Finally a greenstick fracture occurs sometimes in children because their bones are not brittle and do not always break clean across. They partly break like a green stick.

Depressed fracture of the skull is where the vault of the skull has been struck and dented. Many problems arise since the brain is inevitably compressed and no dressing of the accompanying wound should be allowed to press on the brain. The dangers of infection here are not only to the broken bone but to the meninges covering the brain causing meningitis.

Fractured base of skull often passes through that part of the base through which the internal carotid channel runs. Thus it frequently results in blood or cerebrospinal fluid or a mixture of both emerging from the ear. The gravity of this fracture lies in the severity of the impact necessary to produce it which will probably have also caused great destruction of delicate brain tissue. The outlook is usually very poor.

Remember that most casualties with fractures will require a general anaesthetic on arrival in hospital so that their fractures can be set in plaster or otherwise treated. Avoid giving them things by mouth such as drinks which will mean a three hour wait before anaesthetic can be administered.

Burns and Scalds

The severity of a burn or scald depends largely on its surface area. If a patient dies of a burn, the cause of death is either infection or shock.

the latter being due to fluid loss from the surface. Both hazards depend on surface area since the bigger the surface the more germs are able to enter and the more fluid can be lost. It follows that the small burn on the hand or arm is seldom a threat to life however deep the injury and we shall therefore confine our attention to the larger burns of the whole surface of the limb or trunk. Smaller bodies have a relatively larger surface area and so a burn of the surface of a child's limb or trunk represents an even greater risk from fluid loss than a corresponding burn in the adult. Everyone has seen the fluid form in the blister of an ordinary small burn. It comes from the fluid part or plasma of the blood stream and the loss into such a blister may amount to a thimbleful. This will not hurt anyone. But the loss of similar fluid from the surface of a large burn may amount to many pints. The resultant shock will be partly due to this fluid loss from the blood stream resulting in a reduction in blood supply to the brain. Thus shock from burns has common features with shock from haemorrhage and it is treated similarly by transfusion. This time it is not a transfusion of blood but of plasma or some plasma substitute. In practice it is not only water that has been lost but a number of important chemicals dissolved in it as well so that transfusion solutions have to contain sufficient of each individual substance to restore the deficit. The arrangements for replacing the lost materials are complex and urgent every bit as urgent as after a haemorrhage and for the same reason. The brain cannot be left too long in need. In general the First Aid treatment of burns of large surface area is to keep them clean with a dry dressing and get them very quickly to hospital. Life saving treatment by transfusion cannot start until they arrive. The only permissible delay is in the case of burns caused by corrosive chemicals which must be thoroughly washed off before transport so that they do not continue to burn the patient on the way.

Unconsciousness

It is not sufficiently appreciated that the dangers of being unconscious can often far outweigh the dangers from the cause of the unconsciousness. For example it is known that as many as half the deaths from head injuries are due to the airway becoming obstructed and not to the injury itself. The most important thing in managing the unconscious patient from any cause is to preserve an airway. Particularly if the patient is lying on his back it is likely to get blocked

- (a) by his own tongue as the lower jaw sags backwards
- (b) by his dentures (so remove them)
- (c) by vomit and
- (d) by anything anyone may be tempted to give him by mouth

Nothing whatever should be given by mouth in any circumstances to the unconscious patient since he cannot swallow and it will inevitably go into his lungs.

Many of these dangers can be very much reduced by not having him on his back. Place him instead in the semi prone position, half on his side, half on his front with the upper leg drawn up to prevent him from rolling about. In this position the head will be inclined downwards. The jaw will tend to sag forwards and the tongue with it away from the back of the throat. Any vomit will also come forwards. If the tongue does get in the way of the breathing the airway can usually be cleared by bending the head backwards as far as it will go and pushing the whole lower jaw forwards by pushing from behind the angle of the jaw on both sides.

DRUG ABUSE AND DRUG DEPENDENCE

This section of earlier editions of *Pears* was simply called *Addiction*. This word is still much used but is gradually being replaced by

the terms in the present title because ideas about the nature of the problem and methods of dealing with it are changing. *Addiction* is a word that conjures up rather 19th century ideas in the minds of readers. Opium dens, inscrutable orientals, Sherlock Holmes detecting himself with cocaine—basically a phenomenon of foreign origin rather frightening if its implications were not literary rather than factual and not of great significance in Great Britain.

Drug Abuse

It is now realised by doctors, research scientists, social workers and the police—if still not by society as a whole—that the truth is quite different. The abuse of drugs in this country is at present of large proportions, increasing rapidly and showing no signs of diminishing. It is responsible each year for thousands of deaths by suicide and by accidental overdose, for an enormous but virtually unmeasurable amount of private suffering and for the loss to society in terms of reduced working efficiency of millions of man hours every year. It has nothing to do with opium smoking which was never in any case more than the eccentricity of the few. Opium is virtually unused in medicine these days and the amount of smuggling always small, is now negligible. The problems today arise chiefly from the misuse of drugs given by doctors for their effects on the central nervous system—the pain killers, sleeping pills, stimulants and tranquillisers.

Drugs and Medicines

To the doctor any substance is a drug that can be introduced into the body from outside and that is capable of producing some detectable effect. Most such substances have a beneficial use. They are medicines and as such are given by doctors in suitable cases. Others for example nicotine (in cigarettes), alcohol (in beer, wine or spirits) and carbon monoxide (in coal gas) are of doubtful benefit and of certain harm and are used by doctors if at all only under certain very special and usually experimental conditions.

Medicines may be classified under four main headings. First, there are those like quinine or penicillin and other so called antibiotics that actually cure diseases by eradicating the organism (bacteria or other parasites) that cause disturbance of normal bodily function. Second, drugs such as insulin or the steroids overcome in the unhealthy the lack of some necessary substance a healthy body manufactures for itself; they must usually continue to be given for life. Third are the drugs which relieve the signs of disease—for example there are many new drugs that lower the blood pressure or increase the output of urine—without being able to put right the disturbed basic situation which is the cause of the trouble. Fourth are drugs to relieve the patient's symptoms—which make him feel better, less breathless, take away his pain, help him to sleep and so on—although we seldom know why they are able to do this. Indeed in many cases we suspect that they are acting mainly as a token of help from doctor to patient and so encouraging his body to fight a more successful battle on its own behalf. (There is in fact a fifth class of drugs which includes the majority of those on the market at any time, the members of which are devoid of any action whatsoever except that of enriching those who manufacture and sell them but we are not concerned with these at the moment. They constitute a related, but different kind of problem.)

There is no doubt that the genuine advances in beneficial drugs during the last thirty years have been enormous, but the very successes of the penicillins, tetracyclines, antimalarials, hormones and so on have bred in the public and in the medical profession itself an attitude of uncritical wonder. There have been relatively few drugs in the first and second categories mentioned above and in the field of mental health, the importance of which is now so rightly emphasised, there are virtually none. Yet drugs which act

upon the brain are often received as if they were curative although they may pose fresh problems rather than solve the old. Thus although there are many drugs which act upon the mind, few do this in any fundamental sense: they relieve pain and anxiety, bring sleep and lessening of stress and may allow the patient to recuperate himself during the relief they provide. But often this deeper change does not occur—sometimes because the doctor has not clearly seen his part in helping to bring it about—and then the symptomatic relief may come to be sought for its own sake.

New and old drugs are still prescribed for their effects upon the mind—less so now than even a few years ago before the thalidomide disaster—without sufficient attention to possible long term dangers of which there are in effect four.

Dangers of Long term Medication with Drugs acting on the Brain

1 *Toxic effects* Drugs which act upon the nervous system like any others have characteristic toxic or unwanted effects of their own (incidentally these may become apparent rapidly even on rare occasions after only a single dose). Such effects may have little or nothing to do with the desired effects for which they are being prescribed and taken. For example it has only come to be realised quite recently that aspirin is liable to cause bleeding which is occasionally serious from the lining of the stomach in a large proportion of people who take aspirin regularly or that phenacetin another substance very frequently present in pain killers that can be bought from chemists without prescription leads (after prolonged use) to kidney damage. Some drugs may cause rashes and other allergic reactions in susceptible subjects and jaundice, fainting tremors and motor disorders are known to occur in some patients taking a variety of other drugs.

2 *Rebound* The body works in such a way over a variety of its activities that it tends to return to a neutral position after it has departed from this for any reason. For example over eating tends to be followed by a lessening of appetite at least for a time, the runner makes up for his exertion during the race by breathing more deeply thereafter and if at rest you breathe for a time more rapidly and deeply than you need this period will be followed by one in which you breathe less often than usual until the balance is restored. These illustrations—and there are others—have nothing to do with drugs but in a similar way it seems that if a continued pain or an unpleasant emotional state such as anxiety or depression is changed into its opposite or removed altogether by the use of a drug the prior state may return with increased force when the drug is no longer taken. The rebound phenomenon naturally encourages the patient to take another dose and so on.

3 *Habit formation* This alternation of mood changed by drug with the disturbed mood itself leads to the habit of taking the drug. The patient comes to rely upon it and to take it anyway even before the unpleasant state has returned. At this stage he is said to be habituated, he has a psychological need for the drug and later may become disturbed at the possibility that it will not be available when he needs it. This may not matter so greatly if it were not that continued use of drugs in this way has physical consequences as well.

4 *Tolerance and habituation* The body also tends to restore its own balance when drugs are given too. It learns surprisingly quickly how to deal with substances with which it has never before been confronted so that it eliminates subsequent doses more and more quickly and completely. Thus the effect of each successive dose is smaller and lasts for progressively shorter periods of time. To counter this the patient

tends to increase the dose and the vicious circle continues. At this point he has become physically dependent upon the drug and he may suffer physically—sometimes so severely that he dies—if supplies are not continued.

As he increases the dose in this way so his tolerance of its effects increases to such an extent that after prolonged use he may be taking doses of a drug that are five or ten times greater than those which will kill somebody not dependent upon them in this way. It sometimes happens that a patient develops a renewed craving at some point after a course of treatment in which the dose of drug has been reduced without removing the underlying cause of his dependence. He may then obtain and use the dose he has truly took before treatment not knowing that his body will have lost its tolerance of such doses. That dose is now as high for him as for any other person and so may be lethal. There has been a number of deaths for this reason.

Factors in the Causation of Dependence

The risk of becoming dependent upon a drug is governed by three main factors: the drug itself, the personality of the individual who takes it, and the circumstances in which it is taken. Most adults have taken alcohol at one time or another unless it is against their code to do so, yet relatively few are dependent upon it (relatively few but many too many perhaps half a million in the United Kingdom alone). Many of us have had morphine or some other strong pain killer for medical reasons without becoming dependent upon it (whatever so called addicts say it is extremely rare for anyone to become dependent on an opiate because he was introduced to it in a medical setting). On the other hand if we start to take such a drug for kicks—as more and more people, particularly teenagers and young adults are doing—it is extremely probable that we shall become dependent upon it and sooner rather than later at that. It is also probable that each one of us would become dependent were he obliged to take it regularly for long enough and in sufficient dosage. Thus although there are personalities—psychopathic immature or unstable—that are more prone than others to become dependent if they are exposed to the drug there are also drugs that are more likely than others to cause such dependence no matter to whom they are given. The extent of the dependence will vary with some it is never physiological but remains psychological (but not the less real or disturbing for that). Also the rate at which dependence develops may vary and the picture presented by the dependent subject—the extent to which his normal life is impaired or to which he becomes dangerous to himself or others—varies as well. In a very much oversimplified way some of these relationships will now be summarised for certain substances.

Heroin, morphine and cocaine are usually injected. Barbiturates (sleeping pills) and Amphetamine (Benzedrine) are tablets or capsules, and Marijuana (reefers, hashish) is smoked in cigarettes. Heroin and cocaine are now usually taken together. Combinations of drugs often act differently from their individual constituents and patients dependent upon them are even more difficult to treat. Barbiturate and amphetamine also are often mixed (as in purple hearts). There is considerable psychological dependence on heroin, morphine, cocaine and amphetamine, but much less with marijuana. Physiological dependence is great with heroin and morphine, less with barbiturates, alcohol and amphetamine in that order and virtually nil with cocaine and marijuana. Personality plays a greater part in initiating dependence on alcohol, marijuana and barbiturates than with the others. Heroin, cocaine and morphine are the cause of more antisocial tendencies in dependent people than alcohol, barbiturates, and amphetamine. The chief danger of marijuana (mere possession of which is illegal) seems to be that the search for it will lead the searcher into localities where his risk of exposure to even more dangerous influences is greatly increased. It is thus some

times argued that if it were legal to consume marihuana the number of young people who yearly become dependent upon the other more dangerous drugs would in fact decrease. There is as yet no evidence for or against this proposition. The number of drug dependent people in U.K. is rising fast for heroin and cocaine. This number is very large for alcohol and is increasing in the case of barbiturates and marihuana. Very few people are dependent on morphine and the number is not growing.

Treatment

Exhortations imprisonment and other moralistic or legistic approaches are useless. Treatment of any person dependent upon a drug is a matter for a qualified psychotherapist. It is liable to be time consuming and fruitless for patient and doctor and it is frequently unsuccessful. At present there are too few specialists or centres where treatment can be obtained although it is to be hoped that this situation will change as the problem is increasingly seen by our society to be of exceptional gravity.

When there is little or no chance of cure prevention is certainly the best treatment. Drugs should only be taken on the prescription of a doctor and the patient should remind him from time to time if this be necessary that he would like to dispense with his drugs as soon as the doctor thinks it possible. It should also be remembered that there is often no need to reach for the aspirin (or any other drug that anyone can buy from the chemist without prescription) at the first sign of a headache—or to reach for it at all to help one sleep or relax for which purpose such drugs are in any case pharmacologically useless. A wait for ten minutes is good discipline and will frequently resolve the problem to an extent that makes a drug unnecessary.

DISEASES OF THE BLOOD

INTRODUCTION

There are about eight or ten pints of blood in the adult human body. Its main function is to transport nutrient materials to all the various tissues and to carry waste products of tissue activity to organs such as the lungs, kidneys and liver for disposal. It also helps to maintain a constant chemical environment for the body cells, some of which would be very disturbed in their function if the correct balance of organic and inorganic chemicals were not maintained. The blood also serves a protective function in fighting disease either with certain of the white cells or by means of immune antibodies dissolved and carried in the plasma.

A little more than half the volume of blood is the fluid plasma, in which are dissolved all the nutrient materials, organic and inorganic chemicals, hormones and large quantities of protein. The remainder consists of red cells, white cells and some particles which are not really cells called platelets. In every cubic millimetre of whole blood or in every droplet the size of a pin head there are about 5 million red cells, between 5 000 and 10 000 white cells and 200 000 platelets as well as half a cubic millilitre of plasma. The red cells suffer a great deal of wear and tear as they are hurried round the circulation and they only survive for three or four months. There is a red cell factory in the bone marrow which replaces them at exactly the rate they are destroyed and you have made very many millions of new ones while you have been reading this single paragraph. The function of the red cells is to carry the oxygen from the lungs to the tissues and to play an important part in carrying the waste gas carbon dioxide in the reverse direction. A shortage of red cells and hence of their oxygen carrying pigment haemoglobin is called *anæmia*, an excess is called *polycythæmia*.

There are five kinds of white cells or leucocytes: neutrophils (or polymorphonuclear leucocytes), eosinophils, basophils, lymphocytes and mono-

cytes. The first three are quite actively motile like amoeba and are capable of ingesting bacteria and other particles by phagocytosis. There is a great increase in the number of neutrophils (a leucocytosis) during bacterial infections and other inflammatory conditions like appendicitis. Eosinophils are found in larger numbers than usual in allergic conditions like asthma and in infestations by worms and other parasites, but we do not know why this should be. Lymphocytes are concerned with the manufacture of antibodies. In some infections particularly tuberculosis and viral infections there are fewer white cells than usual (leucopenia). Pus consists of the dissolved remnants of inflamed tissue and many dead neutrophils which have become casualties in the battle against infection. It also contains surviving bacteria and as such is a source of further infection.

Platelets are curious particles smaller than any of the cells. They are little pieces broken off certain special bone marrow cells which produce them. They have a role in the stemming of blood loss after injury partly because they are sticky and adhere to one another and to broken blood vessels and help to plug the open ends of damaged vessels and partly because they contain a great deal of a substance (thrombokinas) which is necessary to the clotting mechanism of the blood.

Hematology is the study of blood and its diseases is called is a very complicated subject and only a brief general account will be given here. Diagnosis is usually made by taking small samples of blood (or of the bone marrow where blood cells are made) counting the numbers of the different cells and examining their appearance under the microscope. We shall briefly consider the main diseases involving red cells, white cells and platelets.

Red Cell Diseases

These are of two main groups leading to a shortage of red cells (*anæmia*) or an excess (*polycythæmia*). The former is much the more common and there are many different kinds. In all of them the shortage of red cells results in a depletion of the capacity of the blood to carry oxygen. This means that the heart must work harder to send more blood than usual to the tissues and even so the tissues will often go short. The patient will be persistently tired and listless and if the *anæmia* is severe the action of the brain and heart will be seriously impeded even leading to fainting, cardiac pain and breathlessness on exertion. All these symptoms however can be caused by many other conditions. The only way to be sure they are due to *anæmia* is by a proper examination of the blood and even this will not lead to the truth if the picture has been spoiled by the patient taking iron tonics and other remedies of his own accord. Therefore do not dose yourself with tonics in case you really have *anæmia*. You may make it impossible to arrive at a proper diagnosis later.

Hæmorrhagic Anæmia. *Anæmia*, a shortage of red cells may be due to a variety of causes singly or in combination. One very obvious cause is loss of blood or hæmorrhage. Following the sudden loss of a pint or two of blood or more the red cell producing bone marrow factory will step up its production but even if it is adequately supplied with all the raw materials such as iron it may well take many weeks to build up the numbers to normal. A very severe degree of hæmorrhagic *anæmia* is usually treated by blood transfusion. Milder degrees can be treated by taking extra iron often over a long period of time. The supply of iron for making new red cell pigment is nearly always the bottle neck which limits production. Hæmorrhagic *anæmia* can commonly occur however without a sudden severe hæmorrhage. From what has been said about the constant replacement of red cells as they wear out it must be obvious that even if there is only a slight failure to keep pace with the numbers lost several

month, of such a failure can eventually deplete the numbers to the level of very severe anaemia. This situation is common when small amounts of blood are being continuously or repeatedly lost and here again it is a shortage of dietary iron which is the usual cause of the failure to replace the lost red cells. Normal menstrual loss in women and girls whose diet is on the border line of iron deficiency is a common cause of progressive tiredness and lack of energy. Where the menstrual flow is heavier than usual or where it is frankly excessive in older women due to the various common gynaecological disorders serious anaemia is surprisingly common. During pregnancy a great deal of iron is lost by the mother to the baby and this together with the inevitable blood loss at delivery often makes for a very tired mother indeed just at the time when there is an enormous amount of work to be done to manufacture milk and attend to all the extra household tasks of baby care. For these reasons it is almost routinely advisable to build up stocks of iron throughout the pregnancy by remembering to take the pills provided. Men as well as women can lose small amounts of blood continuously in later life from gastro-intestinal conditions such as piles, ulcers and tropical infestations such as hookworm and here again the anaemia may be just as severe in the long run as that which in evitably follows a sudden massive haemorrhage. One extra word of warning. Do not assume because you are pale that you are anemic. Pallor is a very poor guide because it is dependent on so many other things like the blood vessels in your skin and its thickness and translucency. Nothing but a blood test (which is so easy for your doctor to do) can really tell you if you are anemic. And if your anaemia is due to a blood losing condition then that too must be treated. So do not be tempted to treat yourself and never delay seeing your doctor about any excessive or unexplained bleeding from any source.

Hemolytic Anaemia occurs when for any reason there are more blood cells than usual being destroyed in the body. This may be because the cells are abnormally fragile or because normal cells have been attacked by something to which you are allergic or rarely because you have become sensitive to your own red cells. Sometimes unborn babies have severe hemolytic anaemia due to an incompatibility of blood group (Rh factor) between the mother and the baby and the same sort of thing happens if incompatible blood is given by mistake in blood transfusion. Up to a point in mild hemolytic anaemia the bone marrow can keep pace with the increased loss of cells but beyond this point anaemia develops. After incompatible blood transfusions a very dangerous situation results from the effects of the destruction of red cells and the liberation of their products into the blood. One form of jaundice is often produced in hemolytic anaemia the patient becoming yellow because of the breakdown products of red cells circulating in excess as bile pigments. These latter are normally always present to a small extent due to the normal comparatively small rate of destruction of effete red cells.

Aplastic Anaemia is the term given to anaemia due to a virtually total failure of the bone marrow red cell factory. Sometimes this occurs for no obvious reason. It is sometimes due to a heavy dose of radioactivity or X rays knocking out the cells of the factory. It may even be due to cancer cells growing in the bone marrow cavity and not leaving sufficient room for the red marrow cells. It is fortunate that aplastic anaemia is very rare because it can only be treated by blood transfusions every few weeks for the rest of the patient's life. Very occasionally there have been exceptions to this rule when the patient's marrow has been awakened for no apparent reason and suddenly begins to make red cells again.

Pernicious Anaemia. This is a fairly uncommon anaemia which has a very interesting story. The processes by which red cells are manufactured

are many and complex and depend like so many other bodily activities on the supply of a vitamin containing cobalt called vitamin B₁₂. This is nearly always present in more than adequate quantities in the diet but in order for it to be absorbed from the intestine there must also be a substance called intrinsic factor which is normally made by the lining of the stomach. People with pernicious anaemia have suffered a degeneration of the lining of their stomachs probably because for some reason they have become sensitive to this part of their own tissue. This kind of civil war within the body is known as an autoimmune disease and is comparable in type with some forms of hemolytic anaemia. In other words they destroy their own stomach lining fail to produce intrinsic factor and as a result fail to absorb vitamin B₁₂ into the body. Faced with a failure in the supply of this essential substance the bone marrow produces too few red cells and the few that are produced are deformed, much too large and very fragile. In addition to its role in blood formation vitamin B₁₂ is essential to the normal functioning of the spinal cord and in long standing cases of untreated pernicious anaemia there is often a resulting neurological disability.

The cure for pernicious anaemia was discovered about forty years ago and is a triumph for the scientific investigation of the causes of disease. While treating anemic dogs an American scientist named Minot discovered that eating raw liver in large quantities produced a tremendous improvement. Patients with pernicious anaemia were then made to eat vast quantities of raw liver—about one or two pounds a day—and were found to get better whereas previously they had in evitably died. Raw liver is of course very unpleasant to eat and after a few years it was found possible to prepare crude extracts for injection. Injection had the great advantage that no absorption difficulties arose and much less liver could be used. Biochemists then began the enormous task of trying to find which of the thousands of substances in liver was the vital factor and after many years of painstaking chemical fractionation of liver and trying out the various fractions as a cure for the disease vitamin B₁₂ was discovered. The pure substance is one of the most powerful substances known being active in amounts as small as millionths of a gram. Nowadays pernicious anaemia is treated by small occasional injections of the vitamin, whose other name is cyanocobalamin.

Polycythemia. Too many red cells per cubic millilitre of blood can be found without there being an increase of the total number of red cells in the body. This occurs in dehydration when there is a loss of plasma without a comparable loss of cells, and is called hemo-concentration. Alternatively the bone marrow can manufacture more cells than usual as a response to living for long periods at high altitudes. The beneficial result can be that the blood can carry normal amounts of oxygen, even though the supply (in the rarefied air) is reduced. Finally there is a red cell disease analogous to leukaemia (*qv*) in which the bone marrow factory gets out of control and produces too many cells with no beneficial results. The number in the blood can be double the normal and the blood becomes so thick that the heart has difficulty pumping it round the body. This disease (*polycythemia rubra vera*) used to be treated by repeatedly bleeding the patient to reduce the numbers. It is now treated very successfully with carefully judged amounts of radioactive phosphorus or certain other anti-mitotic chemicals which reduce the rate of multiplication of bone marrow cells. Care has to be taken not to knock them out altogether in which case aplastic anaemia or agranulocytosis (*qv*) could result.

White Cell Diseases

These are fortunately much rarer than diseases involving red cells and are usually much more to be feared.

Agranulocytosis In this condition the number of those white cells which are responsible for phagocytosis of bacteria falls precipitously. The result is that one of the main bodily defences against infection fails and the patient may die from an overwhelming invasion of germs and the accompanying high fever. The usual cause is abnormal sensitivity to certain drugs often those which are in widespread use and only give trouble in the occasional case. One example among hundreds is the antibiotic chloramphenicol which specifically kills typhoid bacteria and is used for that purpose. It is believed that about one case in 60,000 becomes sensitive to it and agranulocytosis often fatally follows. The fact that almost any drug can do this to some people and yet be quite safe for the majority is one good reason not to dose yourself unnecessarily with over the counter medicines.

Leukemia This is a cancer of the white cells in which the normal rate of production of any of the white cells gets out of control leading to a pile up of abnormal cells at the site of production (bone marrow lymph nodes and spleen) or in the blood or both. In spite of an increase in their numbers their abnormality renders them unable to combat infection, sepsis and fever result. It is known that this kind of cancer can be caused by the effects of ionizing radiation on the white cell factory and it is certain at least in animals that viruses can also be responsible. Survivors from the atomic explosions in Japan have subsequently suffered from leukemia far more commonly than the rest of us, as have doctors, nurses and patients who have been over exposed to X rays. At the time of writing leukemia is still a uniformly fatal disease although patients may sometimes survive many years. Their remaining time can nearly always be made more comfortable by various forms of treatment and one day a cure will be found by the research workers devoting their time to its study. It is difficult not to get very impatient with the slow rate of progress of these studies particularly when caring for children and young people whose lives are inevitably ended by the disease. The solution however as with other forms of cancer probably depends on the understanding of the nature of life itself and as long as biological research remains short of the relatively small amounts of money required to tackle these problems at reasonable speed we have no right to be impatient except with our elected leaders who spend far more than is needed on less important things.

Hodgkin's Disease Lymphosarcoma and Reticulosarcoma These are cancerous diseases in many ways similar to leukemia in which the cancer process involves cells of the so called reticulo endothelial system. Such cells are principally in lymph nodes (which used to be called lymph glands) and the spleen. Hodgkin's disease is named after one of the more illustrious pathologists at Guy's Hospital who first described it nearly a hundred years ago and whose early specimens of infected lymph nodes are still preserved there. It is an even greater puzzle than leukemia. There are all grades of severity and although many patients die within six months many survive much longer even for twenty years in some cases.

Hæmorrhagic or Bleeding Diseases

Whenever blood vessels are damaged by injury there is a remarkable series of mechanisms which automatically come into operation to stem the flow of blood. There is a constriction of all the smaller vessels in the locality. Platelets stick together and release substances which help the vessels to stay constricted as well as others necessary to blood clotting and yet others which help to bind the clot tightly together. Later materials appear to prevent too much clotting and eventually the clot is removed altogether as healing proceeds. There are some very complicated diseases of this blood-conserving mechanism which can lead to abnormal bleeding sometimes beneath

the skin to produce bruising or even smaller leaks sometimes leading to a greater loss of blood particularly following a wound. In some kinds of purpura (bleeding tendency) the blood vessels are the cause of the trouble having become fragile and leaky for a number of reasons. This happens in old age (*senile purpura*) in scurvy or vitamin C deficiency as an occasional accompaniment to infective diseases or as an immunological effect on the lining of blood vessels when the patient becomes sensitised to certain substances (*Schönlein Henoch* or *anaphylactoid purpura*). The latter often follows a streptococcal sore throat just as rheumatic fever and acute nephritis do and as well as the purpura there may be joint pains and nephritis. Just as almost any drug or chemical will cause agranulocytosis in some people so it can also cause anaphylactoid purpura.

Purpura may also be due to a lack of platelets known as thrombocytopenia (a shortage of thrombocytes or platelets). This can happen if the bone marrow factory is depressed since this is where platelets too are made. It is therefore a common accompaniment of leukemia or aplastic anemia. Or there can be increased destruction of platelets in some diseases of the spleen. Platelets normally last eight to ten days but their life span can be shortened in heart failure and following massive transfusions or often for no apparent reason (idiopathic thrombocytopenia) when removal of the spleen can sometimes help.

Finally defects of the *clotting mechanism* will lead to a bleeding tendency and since the mechanism itself is very complex so is the variety of things which can upset it. The liver provides the blood with many of the substances required for clotting so it is not surprising that a clotting defect commonly accompanies liver disease. One necessary substance for blood clotting is called anti hæmophilic factor and is missing from people who have inherited the disease *hæmophilia*. These unfortunate people may die of hæmorrhage from quite small cuts or minor surgical procedures like tooth extraction and although it is possible to prepare anti hæmophilic factor it is not yet possible to give continuous life long treatment with it. In emergencies a transfusion of fresh blood (the factor is destroyed by storing) is sometimes used.

DISEASES OF THE HEART AND BLOOD VESSELS

INTRODUCTION

The heart consists of about three quarters of a pound of muscle which makes up the walls of its four chambers. Anatomically the human heart closely resembles the sheep's hearts to be found in a butcher's shop. Indeed it would be an instructive exercise to dissect one of these in the order described below since there is no other way of properly appreciating what the chambers, valves etc. are really like. There are two quite separate pumps in the heart—one on the owner's right (or on your left if you are looking at the front of someone else) and one on his left. The right heart collects spent deoxygenated venous blood which returns there from the whole of the body and gives it the comparatively small push required to drive it through the adjacent lungs. The left heart collects the revitalised oxygenated arterial blood as it trickles away from the lungs and gives it the enormous push required to build up the arterial blood pressure so that it can be forced through all the tissues of the body. As may be expected the right heart chambers have much thinner walls than the left since their muscle has much less work to do. This will help you get your bearings with the sheep's heart. The tip or apex is the lowest part. The thick feeling side is the left, the thin right and the great vessels are at the top.

The upper chamber on the right or right atrium has two large openings into it through which all

the spent blood arrives from the upper and lower great veins (the superior and inferior vena cavae). Cut open the thin wall of the right atrium with scissors between these two holes to lay open the interior of the chamber noting the auricle or dog's ear that forms a small cul-de-sac. The whole chamber is sometimes inaccurately called the auricle. You should be able to push a finger downwards into the lower chamber—the right ventricle—through a communicating hole guarded by the three thin cusps of the *tricuspid valve*. These will not obstruct your finger since they are designed to permit blood flow in the same direction. When the atrium is full of blood it squeezes its contents through the tricuspid valve into the right ventricle and when a split second later the ventricle is full and contracts the three cusps come together to prevent the blood from flowing backwards into the atrium again. Instead the spent blood is driven onwards through the *pulmonary valve* (in the upper part of the right ventricle) through the pulmonary artery to be delivered to the lungs. The pulmonary valve has three very well defined cusps which prevent blood from coming back into the ventricle as it relaxes to receive more blood from the atrium before the next contraction or beat. It is possible to pass a blade of the scissors from the opened out right atrium through the tricuspid valve towards the tip of the heart and cut along the right border of the heart through the thickness of the ventricular muscle. Then cut upwards again passing the scissors blade through the pulmonary valve and open up the *pulmonary artery*. If you have done this successfully you will have followed the path taken by the spent blood through the right heart to the lungs. Notice the thick, round bands of muscle lining the ventricle and notice too that you have not entered the left heart which has no connection with the right except in some congenital malformations (see later). The same dissection can now be made of the left heart. Open up the *left atrium* noting its dog's ear or auricle. Pass the scissors down into the *left ventricle* through the two rather flimsy cusps of the *mitral valve*. Notice how much thicker is the muscle of the left ventricle and cut upwards through the three well formed cusps of the *aortic valve* into the main artery of the body—the *aorta*. The aorta as it leaves the left heart is distinguishable from the pulmonary artery as it leaves the right partly by the extreme toughness of the aortic wall (it has to withstand so much more blood pressure) and partly by the entrances or orifices of the two small branches given off by the aorta just beyond the valve cusps which go to supply the heart muscle itself with blood. These are the *coronary arteries* which are so necessary for the heart's own survival.

The amount of blood pumped in unit time or the *cardiac output* can be varied a great deal according to the needs of the moment. This is accomplished by altering both the heart rate and the stroke volume the amount expelled per beat. Every minute the healthy adult man at rest shifts about ten pints of blood through the heart—a amount equivalent to all the blood he possesses. When exercise is taken or in response to anxiety or fear this is stepped up many times so that the muscles can receive a greatly augmented supply of the materials required for action. The controlling mechanisms which allow these changes to be made automatically are partly organised in the brain by the so called *cardiac centre* and partly by local mechanical and chemical stimuli to the heart muscle itself. The cardiac centre is continuously receiving information through nerves about the physical and chemical state of the circulation and also from the mind which is partly how certain emotions make the heart beat faster. All the information is integrated and a cardiac output continuously arranged which is appropriate for current demands.

Cardiac Neurosis In ordinary circumstances at rest most healthy people are not conscious of their heart beat. However there are many perfectly healthy people whose hearts slip in an extra beat occasionally. Sometimes their owners are aware of this and become unnecessarily alarmed.

Their fear causes palpitations (a pounding of the heart) and the tension mounts. An undue anxiety about the tricks played by a healthy heart sometimes leads people to interpret minor pains in the chest or even indigestion as grave symptoms of heart disease and the consequent anxiety leads to still worse symptoms. If you are one of these worried people take your worries to your doctor and let him decide for you whether there is anything wrong. A hundred to one there isn't and then you will have to find something else to worry about or better still give up the habit altogether. Many people secretly worry about heart disease and high blood pressure for years when very often they are worrying unnecessarily. Even if there is cause for worry, much can be done for the condition (as it can for cancer) provided medical advice is taken early in the course of the disease. Remember too that the slight feeling of giddiness when you get up suddenly from having been lying down is often experienced by most normal people but if you get frightened by it you will learn to breathe more quickly and deeply and this in itself will make you feel even more faint—and so on.

Heart Failure When the cardiac output of blood is too little for the requirements of the body a state of *circulatory failure* has arisen and when this is due primarily to the heart itself being at fault it is more properly called *heart failure*. As will be seen heart failure is not a disease but the common result of a large number of different diseases. The signs and symptoms produced are caused by two sorts of process: (a) tissues of the body have too little blood flow through them and are therefore undersupplied; (b) blood accumulates and stagnates in tissues causing congestion since the failing heart cannot move forward the amount of blood presented to it in the great veins. Often the left or right side of the heart fails disproportionately. In *left heart failure* the lungs are congested because they are the territory from which the left heart is failing to move blood. The patient has great difficulty with his breathing and in advanced cases may not be able to breathe when he lies down horizontally because the lungs become so congested and waterlogged. In *right heart failure* the main veins are congested and other parts of the body become swollen with excess tissue fluid mainly in the lower parts such as the legs and ankles. This swelling with fluid is called *oedema* and in heart failure is only partly due to the mechanics of the failing heart. It is mainly due to a poorly understood retention of sodium in the body a situation in which excess water is also retained. Whatever the type of heart failure it is always likely to be a changing condition since the amount of failure will depend as much on the demands being made as on the state of the heart. For instance in mild cases at rest when the required cardiac output is small there may be no signs or symptoms. These may only appear on exertion. Heart failure will be referred to again later under the various conditions which cause it.

Treatment of heart failure is quite logical. It is aimed at correcting the imbalance between supply and demand of blood and at the removal of the accumulated excess fluid. We can therefore (a) reduce the body's demand for blood, (b) increase the supply or cardiac output and (c) promote the excretion of sodium and fluid. Demand for blood is reduced by rest, both physical and mental, and by reduction of weight since obesity (being overweight) is an additional demand on the cardiovascular system. The cardiac output can be increased by administering a tonic to the heart muscle in the form of *digitalis* which is a powerful heart stimulant derived from fox glove leaf. Fluid (and hence salt) accumulation can be helped by restricting the intake of salt and by giving drugs which promote its excretion by the kidneys (diuretics). Very occasionally very large accumulations of fluid in the legs, abdomen or thorax are tapped and drained physically with needles. These remarks on treatment as elsewhere in the Medical Section, are of course very general and must not encourage anyone to treat themselves for such a potentially serious

condition as heart failure. Even such a simple measure as doing without salt can be practised quite unnecessarily by many people for years simply as a result of reading a paragraph like the above. The most they accomplish is to make their food taste horribly dull. If you need to reduce salt intake you should be in your doctor's care and so please let him decide.

Congenital Heart Disease It has been estimated that of all the babies born who survive at least one month there will be about one in every two hundred with some form of congenital heart disease—that is to say that the heart will have failed to develop properly in embryonic life. In some cases this is associated with a virus disease of the mother (commonly rubella or German measles) or with certain drugs taken by the mother (e.g. thalidomide) at a time very early in pregnancy when organs are assuming their adult shape. Parents should see to it that their daughters get German measles before they grow up and drugs of all kinds should be avoided where possible during early pregnancy. In most cases of congenital heart disease however there is no known cause and it seems that the manner of formation of the embryonic heart is so delicate that it can be thrown out of gear very easily perhaps even by chance. Scores of different types of defect occur singly and in combination. Any of the valves may be anatomically defective—either failing to close properly (*incompetence*) or being too tight (*stenosis*); the great vessels (pulmonary artery and aorta) may be switched round or transposed so that they emerge from the wrong ventricle; there may be defects in the wall (*septum*) which separates the atria or the ventricles on each side (*septal defect* or hole in the heart); or there may be a persistence of the vessel which in the foetus normally by passes the lungs by joining the pulmonary artery to the aorta (*patent ductus arteriosus*). This vessel normally closes at the time of birth when the first breaths are taken and subsequently disappears so that the whole output of the heart is then sent round the lungs. Detecting congenital heart disease early is one of the purposes of routine post natal check up examinations of the baby. Exact diagnosis requires very complicated techniques and sometimes the structural defect can be corrected by surgery with almost miraculous results.

Rheumatic Heart Disease Acute rheumatic fever is not to be confused with other forms of rheumatism. Many tissues of the body (particularly the heart) are attacked as well as the joints and the trouble is due to a sensitivity which has developed to certain bacteria (*haemolytic streptococci*) which have probably caused a sore throat about three weeks before the onset of the disease. Why acute rheumatism only rarely follows streptococcal sore throat is poorly understood but this is no consolation to the one per cent or so of the population whose hearts bear its scars. During the acute phase of the illness which usually occurs before the age of fifteen inflammatory damage occurs to the valves the heart muscle and the sac in which the heart lives the *pericardium*. So there is a *valvulitis* or *endocarditis*, a *myocarditis* and a *pericarditis*. There may be acute heart failure at this stage if the heart is severely affected. The better known results of rheumatic heart disease however are caused in the ensuing years by scarring of the healed valves. The valves are thickened and deformed. They may have lost their elasticity and stretch so that they do not close properly (*incompetence*) or they may contract and tighten (*stenosis*). In both cases the heart chamber situated next to the affected valve has to work progressively harder either because it gets no rest in between beats (*incompetence*) or it has to force the blood through too narrow a hole (*in stenosis*). The end result is some variety of heart failure (P27). Although there are other causes of valvular heart disease which will now be mentioned, rheumatic fever is much the commonest and much valve trouble can be blamed on rheumatic fever even when the patient has no recollection of ever having suffered

from it. The other much rarer causes may be syphilis, congenital valvular anomaly, healed bacterial endocarditis, atherosclerosis and mechanical injury.

The most commonly affected valve is the mitral usually causing *mitral stenosis* in which the opening between the left atrium and left ventricle will sometimes only admit one finger tip instead of three fingers as it should. In time the left atrium becomes much enlarged as it overworks to force blood through this narrow orifice. Later still a back pressure develops in the lungs causing congestion and breathlessness and even later the right ventricle is strained as it tries to force blood into the already congested lung. This is a classic example of the march of trouble backwards from the site of the damaged valve involving first the chamber behind it (the left atrium) then the territory behind that (the lungs) then the pulmonary arteries taking blood to the lungs and finally the right ventricle trying to send blood to the pulmonary artery. This steady march of events is usually very slow and can commonly take twenty years or longer from the initial attack of acute rheumatism to the severer symptoms of advanced mitral stenosis. Treatment is both medical and surgical. The heart failure is treated medically as already described. These days surgical reopening of the valve is almost common place either by inserting a finger through the left auricle and breaking down the constriction or by opening up the heart and re-shaping the valve under direct vision. The latter involves the additional problem of by passing the heart by the use of some sort of external pump and poses additional problems even though from other points of view it is obviously more convenient. As always with major surgical procedures much of the problem is in selecting the patients who will benefit from the operation and in whom it is feasible. Quite often there are other valves involved, mainly the aortic or tricuspid or both and the hydrostatic or plumbing problems can be extremely complex. With luck however combined with good judgement and good surgery the lives of incapacitated patients can be transformed by mitral and other valvular surgery. The aortic valve is stenosed or narrowed by other degenerative processes besides rheumatism. *Tricuspid stenosis* is nearly always rheumatic in origin.

Coronary Heart Disease This is the term used whenever the blood supply to the heart muscle (through the coronary arteries) is reduced to such an extent that the heart muscle suffers from a lack of supplies. It has a number of causes but the only really common one is partial obstruction of the coronary arteries by a condition known as *atheroma* or *atherosclerosis* and sometimes inaccurately called *arteriosclerosis*. This arterial disease is described later (P30). It takes the form of swellings or lumps on the lining of the artery which if they become large enough to interfere seriously with the flow of blood produce a blood starvation or *ischaemia* of the tissue being supplied. Obviously the smaller the artery the more easily will a lump of given size impede the flow. Equally obviously the greater the demand for blood, as in exercise, the more blood starvation there will be. There are two degrees of coronary artery disease one in which the blood flow is reduced to the point where the increased demands of hard work cannot be met and this results in *angina pectoris* due to *coronary insufficiency* the other is when the coronary artery becomes completely blocked preventing the flow of blood altogether usually by a *thrombus* or clot of blood and this is *coronary thrombosis*.

Angina Pectoris Whenever activity is increased in any muscle the demands for oxygen and nutrients from the blood stream increase and as these are used up there is an increased production of waste products known as *metabolites*. To meet these demands for a greater supply and a more efficient waste-disposal, the blood flow through the exercising muscle must always be increased. If sufficient increase does

not occur not only will there be a shortage of supplies but there will also be a pile up of metabolites in the muscle which cannot be carried away. It is mainly because of these latter that pain is caused in ischaemia or blood starved muscle and pain is one of the chief symptoms when heart muscle becomes ischaemic. One important mechanism for increasing blood flow normally to exercising muscle is by an automatically dilating the vessels concerned. Diseased vessels such as coronary arteries when they are affected by atheroma are not so easily dilated although certain drugs which are powerful dilators of arterioles can accomplish a great deal albeit temporarily. The measures taken to relieve the pain and blood starvation of angina are two fold. The patient can reduce the demands of the heart by a few minutes rest and a drug (usually nitroglycerin) can be taken to dilate the coronary vessels of supply. Another obvious long term way to reduce demands is for the overweight patient to eat less and reduce the load of extra body weight on his circulation. It is very frustrating to say the least that such an incapacitating and often lethal condition should be caused by the narrowing or blockage of only two or three inches of narrow piping about one eighth of an inch wide. One obvious form of treatment in theory would be surgical replacement of the piping (many larger arteries than these in other parts of the body are commonly replaced already) or surgical removal of the obstructing inside it. It is very likely that surgeons will one day overcome the technical difficulties involved.

Heart Attack or Coronary Thrombosis It should readily be understood from the above description that heart attacks will vary in severity according to the amount of heart muscle deprived of blood and this in turn will depend on where in the coronary artery the obstruction occurs. Most usually it is the left ventricular muscle which is cut off from supplies and dies either in part or in all of its thickness. Since it is the left ventricle which does most of the work of pumping blood to the body serious heart failure (P27) is to be expected. If too much muscle is killed the heart will simply stop and the patient will suddenly die. It is much more usual however for enough muscle to be left for survival albeit with a greatly reduced cardiac efficiency. A heart attack is usually accompanied by severe pain similar to the pain of angina but more severe and unrelieved by rest or by the patient's usual drugs. Very occasionally the event occurs apparently without pain or with so little that it is ignored. These so called silent coronary attacks can make diagnosis extremely difficult. Since the doctor depends very considerably with heart attacks on an exact spontaneous description of symptoms for his diagnosis no description will be given here. There are many over anxious people who will read these words and could be misled into an unsuspicious description of their own symptoms and this could make the task of treating them such a problem that they could even be misdiagnosed as a result. If you have the smallest worry that your chest pain is due to your heart take your anxiety to your doctor without delay. He will almost certainly be able to reassure you and if it happens to be your heart after all you will have taken the first sensible step towards proper treatment. Dangerous as heart attacks are they are by no means the death warrant that many lay people think any more than cancer is. The treatment for a true heart attack is urgent and prolonged. Patients must be at complete rest and their pain relieved quickly. The area of heart muscle they have lost must be allowed to heal with a good firm scar and this can take three months of rest often in hospital.

Blood pressure The blood is normally under great pressure in the arterial system since it is this which forces it into all the tissues of the body. It is therefore no more meaningful to say you have blood pressure than to say you have a temperature. You would be very badly off without Blood pressure which is too high, however can give rise to problems though not always. It is

another of those conditions like angina and cancer which engender much anxiety among people even when they do not suffer from them. I or this reason doctors are often unwilling to disclose a patient's blood pressure and because of this they unjustifiably earn a reputation for unreasonably secrecy. They are thenelves to blame for the general public anxiety. The following true story shows. Twenty years ago a lady in her fifties wished to accompany her husband to a post abroad which was to last four years. All arrangements had been made—the husband resigned his previous job, sold the house etc.—when it was discovered at a routine medical examination that she had a high blood pressure and she was very solemnly advised by the rather elderly doctor not to go. There was great consternation and emotional upheaval not least because of the inconvenience involved. Eventually she was allowed to go at her own risk. The husband's job lasted eight years instead of four during which the lady was in no way inconvenienced by her blood pressure except that she worried irrationally about it. On returning home to retire she began to think she had angina and elaborate hospital investigation revealed that as might be expected her arteries were not as young as they used to be. She was undoubtedly suffering from mild angina but not as badly as she thought. The opportunity then arose in her late sixties to go abroad yet again and this she did living a quite strenuous life and one which she enjoyed. At the time of writing she has returned home and twenty years later at the age of seventy three is running a home very actively still with very little inconvenience from her blood pressure. There is no doubt that it has been very high all this time and it is also certain that she will die one day although it may well not be of her blood pressure. How much better it would have been for her not to have been told it was high twenty years ago and to have avoided all these years of anxiety. It is not being suggested here that high blood pressure is a trivial condition but that it is for doctors to worry about rather than patients'. If you ever find out your own blood pressure never try to work out for yourself what the figures mean. It is much too complicated. Finally it should be mentioned that high blood pressure may occasionally be associated with or secondary to certain kidney diseases (nephritis) including a strange condition known as *toxæmia of pregnancy* which lasts only as long as the pregnancy provided great care is taken. Most high blood pressure is however primary and without any known association or cause.

Low Blood pressure Some people seem normally to have surprisingly low blood pressure all the time. There is nothing whatever wrong with this. Indeed it may even be beneficial. At least they are unlikely ever to suffer the effects of high blood pressure. The sudden low blood pressure of circulatory failure or shock (P27) is another matter and must be urgently treated.

Irregularities of the Heart beat How quickly or how slowly the heart beats is largely under the control of the cardiac centre in the brain and the level of certain hormones in the blood. The regularity of the beat however is controlled by the so called pace maker in the wall of the right atrium and by the way impulses from the pace maker travel through specialised conducting heart cells (the bundle of His and its branches) to the ventricles. When any part of this elaborate mechanism is upset either by altering the biochemical or electrical conditions of these specialised tissues or by killing some of them off by deprivation of blood supply in the course of a heart attack, disordered rhythm can result. Increase (tachycardia) or decrease (bradycardia) in rate is nearly always a normal response to exercise or anxiety. Very occasional irregularity such as the mistiming of an occasional beat is also quite normal in some people although many are alarmed by it. Persistent irregularity however is abnormal. Its true nature can usually be elucidated by making an electrical record of the heart beat—an electro cardiogram. The commonest causes

are varieties of coronary artery diseases or rheumatic heart disease.

Pericarditis The heart beats inside a bag or sac. At every beat its outer surface slides against the lining of the sac lubricated by a small amount of fluid. This is the pericardial sac, the *pericardium*, being strictly the lubricated membrane which lines the sac and which also covers the outer surface of the heart. Sometimes inflammation occurs—*pericarditis*—and the sliding surfaces become roughened and even separated by a fluid effusion. Very occasionally so much fluid accumulates that the heart's action is seriously impeded. Pericarditis may be due to infection or to rheumatic fever and it usually overhauls the area of damaged muscle after a heart attack. This illustrates something which people rarely appreciate—that inflammation is not by any means always due to infection by bacteria. The last two varieties of pericarditis are quite free from germs (sterile).

Myocarditis A term loosely applied to disorders affecting the heart muscle. There are lots of very rare causes. The really common ones are due to acute or chronic rheumatic causes or to coronary artery disease both of which are described above.

Endocarditis or inflammation of the lining of the heart is a term loosely applied to any disorder of the valves or heart lining. All varieties of rheumatic valvular disease (P28) are included. Bacterial endocarditis in its several forms usually involves valves already damaged by rheumatic disease. It is a complication which is still much to be feared though somewhat less so now that antibiotic drugs are available.

Atheroma or Atherosclerosis This is the condition referred to above in which lumps arise on the lining of arterial blood vessels. Although it is therefore a disease of the arteries its importance lies in the way blood flow is held up either by the lumps themselves or by thrombosis ultimately blocking the narrowed portion of the pipework. The effects on the body are therefore those of depriving the tissues of blood. It is an astonishing fact that in England and America more people die of the consequences of atheroma than of any other single disease, including all forms of cancer put together. Furthermore, cancer is mainly a disease of old age whereas many of the effects of atheroma on men occur in early middle age. If narrowing of the artery is going to do significant harm it is easy to see that it will be of more consequence in those parts of the body where small bore vessels are supplying tissues whose functions are necessary for life. Exactly such a situation exists in the heart and in the brain. An additional factor is that the arrangement of the blood supply in these tissues is such that any particular area has only one vessel leading to it. This is unusual among the tissues generally where several alternative or collateral vessels usually supply an area and where others can take over if one becomes obstructed. We have therefore a situation in which perhaps the most important tissues—the heart and the brain—run the greatest risk of deprivation and this leads to angina and coronary thrombosis on the one hand and cerebral thrombosis and hemorrhage (stroke illness) on the other, accounting jointly for about one death in every five. In addition the effects of atheromatous narrowing are often felt in the legs where the blood supply to the muscles is inadequate for exercise leading to intermittent pain comparable with that in the heart in similar circumstances. This is called *intermittent claudication* or intermittent closing of the leg arteries. In its most severe forms it leads to the need for amputation although in most cases early treatment can avoid this. It is small wonder that there is intensive research into the causes of atheroma, as with cancer but it is probably true to say that we still know rather more about cancer

A lot of attention has been given to the amounts of certain fats in the circulating blood, particularly cholesterol. This fat is found in larger amounts in the blood of subjects from atheroma and is also found in the arterial lumps themselves. Efforts have therefore been made to reduce blood cholesterol by modifications of the diet but it has been extremely difficult to prove that this has done any good. Many other factors are known to contribute to atheroma and hence to heart attacks and strokes some of which can be reduced and others not. Such factors are age, obesity, high blood pressure and smoking cigarettes. People who lead an active life like bus conductors seem to have less trouble than others who are less active like bus drivers. Sudden severe exercise however is bad if you are not used to it. It is better and life saving to take regular moderate exercise. Women have less atheroma than men until the menopause when they begin to catch up so that hormones have something to do with it. Serious starvation such as occurred in the German occupied territories of Holland and Scandinavia and in the concentration camps conferred one benefit—a freedom from atheroma but obviously we cannot all starve and the puzzle remains. Like many of the more important outstanding medical puzzles there is no single factor responsible and this is what makes it difficult to solve.

Aortic Disease The aorta, the main artery of the body running from the left ventricle down through the chest and abdomen, also suffers from atheroma but is too wide (about an inch across) to become obstructed. However weaknesses occur in the thickness of its wall sometimes due to syphilis but nowadays much more usually due to atheroma which results in a ballooning out of a part of the vessel rather like you sometimes see in an old bicycle inner tube. In days gone by these *aneurysms* as the dilations are called, reached an enormous size and would wear away the breastbone and ribs to appear as large pulsating masses on the chest. Now that advanced syphilis is less common atheromatous aneurysm with a predilection for the abdominal aorta is the one most commonly seen and these days it is treated by replacement of the diseased portion of vessel. *Dissecting aneurysms* of the aorta are another variety in which the blood under high pressure somehow finds its way in between the layers of the aortic wall and then suddenly rips up and down the whole length of the vessel separating (or dissecting) one layer from another in its path. Sometimes it tracks back towards the heart and suddenly fills the pericardium with blood to stop the heart's action altogether.

Embolism This term refers to any foreign object travelling in the circulation and becoming impacted when it reaches a vessel too small for it to pass through. It may be a thrombus (P31) a collection of cancer cells, a group of bacteria, a chunk of infected pus from an abscess, a collection of fat droplets or even a bubble of air. If it originates in a vein it travels to the right heart and to the lungs. If it comes from the left heart or an artery it will impact in any part of the arterial tree. Reasonably enough an arterial embolus will commonly end up in those parts of the body with the richest blood supply like the brain, the kidneys, the liver or the bone marrow. A thrombotic embolus will cause death of the tissue in the area previously supplied by the blocked vessel, a condition known as *infarction*. Perhaps the commonest source of thrombotic embolism is the lining of the heart chambers where a thrombus has occurred at the site of muscle damaged by a heart attack. Massive pulmonary (lung) embolism is usually the result of thrombosis of the leg veins in people kept immobile following surgery or childbirth. That is why postoperative patients are got out of bed for a while as soon as the first day after the operation. The cells of a cancer embolus usually die but if they survive a new cancer deposit begins to grow where the embolus impacts and this is one of the ways cancer may spread. An infected embolus may infect the vessel wall when it impacts producing a weakness

which may give way. An embolism if enough insoluble gas enters the circulation can kill by making so much froth in the heart chambers as to impede the normal pumping action. If bubbles pass the lungs and enter the brain all sorts of neurological disorders like scores of tiny strokes arise. The same sort of thing happens all over the body in the *bends* or *caisson disease* in which the blood literally boils. It is due to a too rapid return to normal pressure from regions of high pressure at great depths or from pressurised chambers. Fat embolism sometimes occurs after fractures due to marrow fat entering damaged veins and being carried away to the lungs.

Thrombosis This is not quite the same as clotting. It is the mass which arises when platelets adhere to the lining of blood vessels or heart chambers. Blood clot accumulates among layers of deposited platelets and the thrombus therefore has structure unlike pure blood clot. Thrombosis usually occurs when the lining of the vessel or chamber is damaged by atheroma or inflammation or when the circulation becomes very stagnant. One danger is that it will become dislodged and travel as an embolus during the first week or ten days of its existence. After this time it is usually firmly incorporated into the vessel walls by cells which migrate into it from the surrounding tissue. The other danger is of course that the tissue previously supplied by the blocked vessel will die before a collateral circulation can be established. As previously explained this is called infarction. All the technical terms in this section are used elsewhere and can be looked up.

Buerger's Disease or thromboangiitis obliterans This is an inflammation of the arterial wall which leads to blockage by thrombosis. The leg arteries of comparatively young men are most commonly affected leading to amputation in some cases. Unlike lung cancer, coronary heart disease and bronchitis which are known to be associated with smoking Buerger's disease is only thought to be. There is a horrible tale of a young man who had lost all his four limbs one after another sitting on the hospital steps begging passers by to light his cigarette for him.

Reynaud's Disease This is a strange condition in which the finger tips and in severe cases all the fingers or the whole hand respond in an exaggerated way to cold. The vessels supplying the hand are constricted and the fingers go white as the blood drains from them. Then the capillaries dilate and become distended and filled with blood. But owing to stagnation it is venous and blue and the fingers are therefore blue. Now we have all experienced this in very cold weather but sufferers from Reynaud's disease nearly always women respond even to very slight cold like putting their hands into cold water. Even emotional stress will start the process off. In very severe cases the fingers will be so deprived of blood for so long that sores will develop and fingers can even be lost but this is very rare and can be avoided by an operation to cut the nerves which supply the circular muscle of the vessels concerned. In most cases it is sufficient to avoid getting the hands cold.

Frostbite Strictly speaking this is literally a freezing of the tissues. Although their freezing point might be expected to be close to that of water it usually only occurs at temperatures below -13°C (5°F). The patient may feel a pricking feeling at first and feel an area of firmer pale skin on the cheeks nose ears fingers or toes. If these parts are rubbed with cold the onset of frostbite may not be felt and will often only be noticed by others. In countries where extreme cold is prevalent it is usual for complete strangers to stop each other in the street and point it out when they see it. It is important not to rub the affected part but contrary to popular belief it must be warmed as rapidly as possible. Fingers should be immersed in water as hot as the normal hand can bear (110°F). Many First Aid books still quote wrongly teach that return to warmth must be gradual.

DISEASES OF THE RESPIRATORY SYSTEM

INTRODUCTION

When air is drawn in during the process of breathing it is brought into very close contact with the blood passing through the lungs. In this way the air we breathe in which contains 20 per cent oxygen is confronted with spent blood returning from the tissues which contains CO_2 and carbon dioxide. At the same time the waste gas carbon dioxide passes by diffusion in the reverse direction from the blood into the air because there is much more carbon dioxide in the returning spent blood than the tiny amount in the air we breathe. The blood is therefore continually circulating through the lungs and exchanging carbon dioxide for oxygen from the air we breathe in. When we breathe out we disperse the carbon dioxide into the atmosphere.

When the air enters the nose or mouth it passes into the windpipe or *trachea* through the vocal cords in the pharynx. The trachea is held open all the time by rings of cartilage and is lined by a mucus secreting membrane covered by millions of tiny hairs or cilia. These continuously waft a sheet of sticky mucus upwards which traps any dust or other small particles we may have inhaled, until a collection of this material in the pharynx stimulates us to cough and expel the phlegm usually to be swallowed. At its lower end the trachea or windpipe divides into two the right and left main *bronchi*. Each main bronchial tube enters a lung one on each side and proceeds to divide repeatedly within the lung until the air is being carried by more and more smaller and ever smaller tubes called *bronchioles*. There are many millions of these on each side and each one end in a collection of very small balloon like structures—the air sacs or *alveoli*. If you were to cut across a lung and examine the cut surface in a good light you would see that it is a spongy tissue with many millions of tiny holes each one just visible to the naked eye. These are the air sacs. In their walls run the blood capillaries each one of which is a branch of the vessels carrying spent blood from the right side of the heart. At this stage the blood is only separated from the air in the sacs by the walls of the capillaries and of the air sacs themselves. Both structures are extremely thin making for easy diffusion of the gases between blood and air.

The action of breathing is accomplished by two muscular mechanisms. One is by the muscles which move the ribs and the other by the diaphragm, a sheet of muscle which runs across the body separating the chest cavity from the abdominal cavity. These muscles are all actuated by nerves, just as all other muscles are. Those running to the muscles of breathing are organised by a mechanism in the brain known as the *respiratory centre*. It is this centre—one of the so called vital centres of the brain—which receives information from many different sources, and translates it into instructions for the breathing mechanism. Thus when you run for a bus you will automatically breathe more deeply and more quickly because the respiratory centre has been informed about all the extra carbon dioxide in your blood which has been produced by the exercising leg muscles. Even the conscious instructions involved when you blow a trumpet inflate a balloon or during speaking all pass first to the respiratory centre. It is the death of the cells of this and other vital centres of the brain that is the ultimate cause of death in everyone who dies.

Bronchitis may be acute or chronic. It is an inflammation of the lining mucous membrane of the larger air passages or bronchi, and results in much more secretion than the amount normally produced mixed with some pus. The acute form is often caused by viruses, with secondary infection from bacteria. It may sometimes be caused by irritant gases like the sulphur dioxide in smog. The chronic or long-standing form of bronchitis is often associated with *emphysema*, in which the small air sacs of the lung architecture

are destroyed or distorted leaving larger spaces than normal often surrounded by fibrous scar tissue. Such an arrangement makes the normal gaseous exchange difficult between air and blood. While the exact cause of chronic bronchitis is difficult to discover because it is such a mixture of causes it is mainly associated with older age groups particularly men in damp foggy climates like ours in Britain with polluted town air and especially with smoking. Smoking also makes any existing bronchitis much worse. Patients cough and produce varying amounts of sputum or phlegm. They often wheeze like asthmatics. This may go on for many years before the right side of the heart begins to fail (P27). Gradually during this time the chest tends to become barrel shaped. Treatment consists of getting the patient to stop smoking, or otherwise contaminating his lungs preventing infection particularly during winter months with germ killing antibiotics and breathing exercises. The outlook for chronic bronchitis and emphysema is nevertheless not good although many patients continue with their disease for many years provided they take constant care to obey instructions and stop smoking.

Bronchial Asthma (not to be confused with cardiac asthma) is a condition in which the finer air passages become constricted due to an allergic response. In addition an increased secretion tends to obstruct them and the patient wheezes. In many cases it can be shown that he is allergic to a particular component of dust or less commonly a foodstuff. This is the same sort of thing as occurs in the upper respiratory passages in hay fever, but the effect is on a different lower part of the respiratory system. Many other cases are due to respiratory infection of some sort probably combined with an allergy to the bacteria causing it. A predisposition to asthma is often inherited. Once a patient has become asthmatic his attacks will be triggered off by such additional things as emotional stress changes in temperature (particularly sudden cold) irritating fumes or smoke and physical exertion. These are secondary factors and although much of the treatment is concerned with them it is unlikely that any of them are a sole cause of the condition. Treatment is directed at the relief of the breathing difficulty and of the wheezing as well as the control of the causative factors. Many useful drugs are available to dilate the contracted air passages and reduce the obstructing secretions. Asthma in children often gets better as the patient grows up. Asthma is another condition made much worse by smoking. Patients should avoid extremes of cold and humidity particularly out door exertion in cold damp weather. They should also avoid exposure to respiratory infection.

Bronchiectasis In this condition the bronchial air passages are abnormally and permanently dilated and the normal structure of the walls destroyed. It is thought to be caused by obstructions of the tubes which lead to dilatation of the parts beyond. Secretions accumulate and since they cannot easily drain away they become infected. The infection helps to complete the process of destruction of structures in the bronchial wall. The patient has a chronic cough which often produces large quantities of purulent sputum and there are often recurrent episodes of pneumonia. Diagnosis is made by a special X ray examination—a bronchogram—in which a material opaque to X rays is dropped into the air passages. This shows up the dilated and distorted tubes. In some cases where the disease is localised to one part of the lung it is often a good idea to cut out that portion and this is particularly true in young people. Vigorous physiotherapy involving drainage of the lungs by placing the patient in a suitable posture together with antibiotic drugs for the infection are other forms of treatment.

Cystic Fibrosis is an inborn disease which affects chiefly the lungs and the digestive system. It is sometimes called *Fibrocystic disease of the Pancreas* and sometimes *Mucoviscidiosis*. Until it was medically recognised twenty-five years ago

children affected usually died from pneumonia in the first year of life. This of course was before antibiotics were available for the treatment of infections. Today cystic fibrosis is known to be the commonest genetically determined disorder affecting children in Britain. One child in 2000 receives one of the abnormal genes from each parent. Such a child therefore has a double dose of the harmful gene and will have the disease from birth. One person in 25 of the general population carries only one of these abnormal genes and such an individual will not have the disease but will be a carrier of the abnormal gene. If such a seemingly normal carrier marries another carrier there is a one in four chance of each of their children being affected. The children therefore who actually develop cystic fibrosis have inherited the disease *equally* from both parents who are carriers but are themselves unaffected by the disease. Although much has been learned about cystic fibrosis in the past twenty five years there remain many unsolved problems and we still cannot define precisely the biochemical fault which causes it. The prospects for survival into reasonably healthy adult life are steadily improving but they depend upon early diagnosis and careful management through childhood. In cystic fibrosis most of the damage is caused by the excessive viscosity or stickiness of the mucus which is produced in the breathing tubes as a lubricant and also in the ducts of the pancreatic gland which provides enzymes to help digestion. Being thick and sticky instead of thin and slimy as in the normal this mucus tends to block the passages instead of keeping them clear. The pancreatic cells are permanently destroyed. The gland cannot secrete pancreatic enzymes and the food especially protein and fat is not properly absorbed. This deficiency can be compensated fairly well by giving pancreatic extract by mouth with every meal and by dietary care.

The major clinical problem is in the lungs. The lung passages normally have a thin coating of mucus which is propelled steadily upwards and is completely renewed in less than one hour. It moves more suddenly on coughing. In cystic fibrosis this upward movement is slowed down and interrupted. There is difficulty in keeping the passages clear especially when infection with bacteria or viruses greatly increases the amount of mucus. This results in intermittent blocking of the air passages difficulty in breathing, incomplete use of the lungs and persistent local pockets of infection. If such infectious processes are not controlled areas of lung will be destroyed. Chronic infection will persist and multiple lung cavities will develop. These predispose to further infection interfering with the natural development of the lung—a process not normally complete until halfway through childhood—thus adding to the respiratory problems which the child will face in later life. Unless a correct diagnosis is made and proper treatment instituted before the first serious lung infection has occurred the resulting lung damage may well be permanent. The Cystic Fibrosis Research Foundation Trust of Stuart House 1 Tudor Street London E.C.4 was founded in 1964 to raise funds to finance research and to help and advise parents with everyday problems in caring for these children.

Pneumonia This is an infection of the lung tissue rather than of the air passages. The lung is the only internal organ which is directly exposed to the air and since there are germs of all kinds in the air it is a source of surprise that pneumonia is not a much more common event in all of us. The answer lies as with all infections in the fact that it is not simply (or even mainly) bacteria which cause disease but our own lack of resistance to them. If we allow germs to thrive and multiply by being unhealthy or run down or undernourished infective disease will occur. If we are fit the entry of those same harmful germs into the body causes us no inconvenience unless we are very young or very old or unless the invasion of germs is abnormally overwhelming. This helps to explain why pneumonia is so often quoted as a cause of death. In most cases it is merely a terminal event occurring in the elderly sick whose normal resistance is so far reduced by their

illness that they succumb to an invasion which they would normally not notice. There are two main kinds of pneumonia and in both the air sacs become filled with inflammatory secretions making the normally porous lung tissue as solid as liver. In *lobar pneumonia* a whole segment (or lobe) of the lung becomes solid. In *broncho pneumonia* areas of lung tissue surrounding the smaller bronchioles become consolidated leaving normal porous lung tissue in between. Broncho pneumonia is the one which occurs in the rather stagnant lungs of people who are already ill or bedridden. Both forms respond to treatment with the appropriate antibiotics provided any underlying debility does not interfere with the patient's own resistance. In the terminal bronchopneumonia of fatal illness it is sometimes considered kinder not to treat the additional pneumonia. *Pleurisy* is a natural complication and before the days of antibiotic drugs *lung abscess* was very much feared. Another form of pneumonia—*virus pneumonia*—has been referred to on P10(2).

Pneumoconiosis This is a term which refers to a large group of different diseases all of which are caused by breathing in some form of dust over a very long period of time. It is therefore an occupational hazard of certain trades. We have already mentioned the mechanisms of mucus secretion in the air passages, which normally trap small particles from the air and prevent them reaching the lung. However in some occupations there is so much dust breathed in over the months and years that these normal barriers are defeated. About a quarter of the earth's crust consists of silicon in quartz flint or sand. *Silicosis* occurs in people who have worked for many years in trades like mining, stone crushing, sandblasting, or metal grinding, who are often breathing silicon dust in high concentration. When the particles arrive in the air sacs they set up an irritant chemical reaction which produces nodules of scar tissue. *Silicosis* for some reason predisposes to tuberculosis (P14(1)). *Emphysema* also occurs and there is a general impairment of respiratory function. *Coalminer's pneumoconiosis* is similar to *silicosis* but not identical with it. It is more prevalent in some coalfields than others owing to the different composition of the dust to which these unfortunate men are daily exposed. It is hoped that modern mining methods will help to reduce this dread disease. *Asbestos* is a complex silicate of magnesium, calcium and iron. *Asbestosis* is caused by inhaling its fine fibres. *Berylliosis* is caused by inhaling compounds of beryllium used in the manufacture of fluorescent lamps. *Farmers' lung* is a pneumoconiosis caused by inhaling hay and grain dust and is similar to *bagassosis* and *byssinosis* caused by sugar cane and cotton dust respectively. The newest pneumoconiosis to be reported is *mushroom worker's lung* caused by something in the compost in which mushrooms are commercially grown.

Pulmonary Embolism This catastrophic yet quite common condition has already been briefly referred to (P30(2)). It is a cause of tragic sudden death in people who have had operations or have given birth to babies some days previously or who have been bedridden for any other cause. The first event is that the blood in the veins of the legs becomes stagnant due to the lack of exercise and together with the tendency to clot which often follows surgery or childbirth the whole length of a leg vein may be obstructed for twelve inches or more by an elongated clot of blood. This does little harm to the circulation of the leg since there are plenty of other veins for returning blood to the heart. The danger is that the clot will become dislodged and be swept upwards towards the heart by the flow of returning blood. When this happens it is carried by way of the right auricle and ventricle into the pulmonary vessels which normally carry spent blood to the lungs. Here for the first time it enters vessels which are getting smaller as they divide and it then impacts in the main pulmonary artery. The patient who may have been recovering very well suddenly collapses and not unusually dies there and then. At autopsy a long coiled up mass of clot is found

obstructing the pulmonary vessels. It often can be seen to form a cast of the leg vein and even bears the marks of the small venous valves which are present at its site of origin. With the dramatic advances being made in chest surgery it is now sometimes possible in selected cases to operate to remove the clot. Success clearly depends on the patient's surviving long enough to be taken to the operating theatre for the major operation of *pulmonary embolectomy*. Three quarters of all cases of pulmonary embolism die within two hours and therefore the best hope would be to prevent the occurrence altogether. This is not at present possible but clotting in leg veins can be discouraged by early exercise following surgery and childbirth. Patients often resent having to get up the next day because it is so uncomfortable. Herein however lies their best hope of avoiding pulmonary embolism.

Haemoptysis This means coughing up blood or blood stained material. I must be distinguished from *haematemesis* in which the blood is vomited from the stomach. It must always be taken seriously because of the underlying lung disease which may be present. No one who coughs up blood in however small a quantity should neglect to inform their doctor so that its source can be determined. *Haemoptysis* occurs in a variety of lung diseases some of which is not serious but much of which must be treated immediately if it is not to become so. This is a suitable place to repeat our general rule that you should see your doctor without delay if you have any unexplained bleeding from any part of the body however well you feel. And this includes haemoptysis.

Fat Embolism Liquid fat sometimes enters the bloodstream following extensive crush injuries to soft tissue and bone. It splits up into millions of small globules which are carried to the lungs and impact in small blood vessels there producing obstruction of the lung circulation and consequent difficulties in breathing.

Lung Cancer This is one of the nastiest and most incurable forms of cancer which can occur. It is also probably the easiest to prevent. There has been no reasonable doubt for several years now that it is associated with cigarette smoking and the evidence is overwhelming. However in spite of this certain knowledge smoking continues to increase and every year there are more and more people dying unpleasantly of lung cancer. It seems that nothing the health authorities can do is able to stop it. Intensive campaigns of public advertising of the dangers and well organised instruction in schools have so far made no impression whatever on the smoking habits even of people who accept the evidence. The only group of people who are known to have stopped smoking are British doctors, very many of whom have given it up and it is easy to show that giving it up has saved them from the disease. Their colleagues who have not done so have continued to die. Undoubtedly a large factor contributing to the failure of anti smoking propaganda is the enormous expenditure by the tobacco manufacturers on very clever advertising amounting to many millions of pounds each year. Moreover they spend a pitiful fraction of this amount on their own research into the harmful effects of their own product which has so far discovered nothing which was not already known by research doctors many years ago. Another problem is that it takes a number of years to get cancer. It is not like an infectious disease which is caught a few days after exposure to the bacteria concerned. It may be fifteen or twenty years before the cancer begins and many smokers are apparently unwilling to look so far ahead. Furthermore not everyone who smokes dies this way and so a smoker can gamble with his life and hope it will not be him. The present writer once had to perform a series of post mortem examinations on people who died of lung cancer and this helped him to stop smoking completely having smoked more than twenty cigarettes a day for several years. Not everyone can have this incentive. The main

encouragement to smoke probably comes from other people. Schoolboys are easily impressed when their teachers and parents stop smoking. They are not likely to fear the habit when these same people smoke openly. The smoking doctor is also a powerful stimulus to people to carry on smoking.

Lung cancer grows in the wall of a main bronchial air passage. If it grows inwards it can obstruct the air way choking that part of the lung it is supplying, with air. This causes collapse and infection of the lung and may lead to *lung abscess*. The patient will then cough up blood stained infected and purulent material. Such a case is comparatively lucky since the disease declares itself early by producing symptoms. In others the lump may grow outwards into the surrounding lung and produce no symptoms at all in the early stages. Indeed it may spread to other parts of the body like brain or bone or liver before causing any trouble to the patient. If this happens he may go to his doctor because of fits changes of personality or fracture only to discover that the origin of the trouble is in the lung.

The chances of cure are negligible although much can be done to relieve the pain and suffering of the last stages of the illness. Not more than one in twenty cases is alive two years after it is first diagnosed. Surgery by removing the lung and irradiation of the growth are the standard palliative treatment. It is not the practice of the Medical Section to alarm the reader unnecessarily but if only a few are induced to stop giving themselves such a horrible disease then writing in this way will have been justified.

Secondary Cancer of the Lung In nearly all forms of cancer the big problem is that it spreads to other parts of the body. If this were not so it could be eradicated by surgical removal more often than it is. One common way in which it spreads from any part of the body is by entering the bloodstream and being carried as clumps of living cancer cells to distant parts. When these come to rest in smaller blood vessels they begin to grow and colonise the new environment. Such new colonies are called *secondary deposits* or *metastases*. It so happens that all veins (except portal veins of the liver) lead to the right heart and thence directly to the lungs and for this reason the lungs are a very common site of *secondary cancer* which may have begun in the bowel or breast or indeed anywhere else in the body. Other common sites of secondary blood borne cancer are the brain, liver, bone marrow and kidney since all of them have an abundant blood supply and there is therefore a high chance of the travelling cells arriving there. Secondary cancer of the lung usually consists of several lumps scattered throughout the lung. Lung cancer itself is usually only one growth. One of the main reasons for the success of early diagnosis is that treatment may be possible before blood borne and other means of spread have occurred. Unfortunately in the case of primary cancer of the lung even early diagnosis is of little avail but in many other common cancers permanent cure is possible if treatment is begun early enough.

Pleurisy The chest is lined by one layer of a thin membrane called the *pleura*. The lungs are covered and enclosed by a second continuous layer of this same membrane. When the lungs move during respiration the pleura covering the lungs rubs against the pleura lining the chest lubricated by a very thin layer of pleural fluid separating the two pleura. Whenever the pleural surface becomes inflamed this is known as *pleurisy*. It is nearly always due to inflammatory disease of the adjoining lung and is therefore not strictly a disease in its own right. For example pneumonia, tuberculosis, lung cancer or a lung infarct (P30(12)) will produce a pleurisy if the area of diseased lung adjoins the lung surface. Sometimes the area of inflamed inner pleura will tend to stick to its outer layer or rub painfully against it producing a sharp pain when the patient breathes. Sometimes a large effusion of fluid is produced which separates the two layers and collapses the

lung by occupying space in the chest which the lung should be occupying. This latter is more usual in tuberculosis or cancer.

The lung can be collapsed by the entry of any thin, between the normally adjacent layers of pleura. For example air can be introduced either deliberately to rest the lung in tuberculous or by accidental penetrating wounds of the chest wall or by accidental rupture of the emphysematous lung (q.v.). This condition is called *pneumothorax* or air in the chest. Bleeding into the cavity between the pleura is called *haemothorax*.

DISEASES OF THE DIGESTIVE TRACT AND LARGE INTESTINE.

INTRODUCTION

The digestive tract consists of the mouth, pharynx, oesophagus (or gullet), stomach, small intestine, large intestine (or colon), rectum and anus. The small intestine is very long and is subdivided into the duodenum, jejunum and ileum. It ends at the junction of the ileum with the caecum, where there is a small blind side tube the appendix. The caecum leads into the colon. The whole tract has two main mechanical functions and two main biochemical ones. Mechanically food has to be chewed in the mouth and further minced up by muscular squeezing mainly by the stomach. It has also to be propelled along by an orderly series of squeezing movements known as *peristalsis*. While it is still in the digestive tract food has to be digested. That is to say it has to be broken down chemically into suitable materials for absorption into the system and secondly it has to be absorbed across the wall of the intestine into the blood stream. itself a highly complex biochemical process. The blood stream it now enters is a special part of the circulation the portal system which travels directly to the liver without first passing to the heart. In the liver the broken down foods are processed and issued in their new form into the general or systemic circulation by which they are finally carried to all the tissues of the body.

As the food passes along the digestive tract (or as it is sometimes called the alimentary canal) it is mixed with various secretions which are either made in the wall of the tract or by organs outside the wall connected to the main pathway by small tubes. Examples of the latter are bile manufactured by the liver and sent into the duodenum through the bile ducts. Also pancreatic juice comes from the pancreas down the pancreatic ducts also into the duodenum. These secretions are either digestive juices concerned with splitting up the foodstuffs so that they can be absorbed or they have a lubricant function so that the gut contents slide along easily under the influence of peristalsis. Roughly speaking it may be said that digestive juices give place to lubricant secretions at the junction between the small and large intestine.

The constituents of the diet are dealt with in a later section. The principle classes with whose digestion we are now concerned are carbohydrates, proteins and fats.

Carbohydrates are sugars and starches. There are many sugars which may exist alone in pairs, or with lots of them stuck together. Alone they are such things as glucose or fructose. Common table sugar is a substance called sucrose formed by sticking one glucose molecule to one fructose molecule. Starch is lots of glucose molecules all stuck together. Digestion of carbohydrates consists of splitting up sugars and starch into single sugars like glucose, since only single sugars can be absorbed into the system. The splitting is done by digestive *enzymes* which are found in the juices secreted into the digestive tract. Sugar splitters are found in the saliva of the mouth in the pancreatic juice of the duodenum, and in the duodenum's own juice from its own wall. On the face of it, you might think it would be better to eat glucose which needs no digestion and can be absorbed in

this form than to eat starch which has first to be split and so a lot of money has been made out of a gullible public by the sale of glucose drinks and powder. In fact digesting starch is no problem whatever even for the sick who can obtain their carbohydrate energy just as easily (and much more cheaply) from potatoes as from expensive glucose. The end result of eating both is the same. The starch-splitting enzyme in saliva is mixed with the food as it is chewed and it is there for probably a good idea to chew it well. However even if the food is boiled it does not seem to matter very much. People without teeth (neither their own nor dentures) seem to digest their carbohydrate quite well presumably by means of their pancreatic juice at a later stage.

Proteins which are found in meat, cheese and eggs have very large molecules consisting of lots of small ones strung together. Unlike starch in which all the component glucose molecules are identical the amino acids of which proteins are composed come in many different types. They all contain nitrogen and there are about twenty seven varieties. One protein differs from another in the proportions of the mixture and the order in which they are strung together. Only single amino acids can be absorbed from the food and so protein digestion again consists of splitting the material down into its building bricks. There is a strong protein-splitting enzyme in the gastric (or stomach) juice called pepsin whose job it is to split the long amino acid chains into shorter chains. Several other protein splitters in the duodenal and pancreatic juice contrive to break the smaller chains into individual amino acids which are then absorbed and sent to the liver for processing.

Fats mainly consist of glycerol to which are attached three fatty acid molecules for each molecule of glycerol. An enzyme in pancreatic juice splits the fatty acids off the glycerol but would have some difficulty penetrating the globules of fat without the help of bile. One of the constituents of bile (bile salts) has detergent properties like washing up powder and breaks the fat globules up into a very fine suspension so that the enzyme can get at the fat. Some fat particles of this size can even be absorbed as such without preliminary splitting.

The processes by which all these enzymic secretions are produced are very finely controlled. They are very expensive to make in terms of energy and raw materials and so it would be very wasteful to produce them all the time even when there was no food to digest. And so the body has some very well designed automatic arrangements for sampling the foods as they are eaten and passed on which ensure that exactly the right kind of juice is waiting in every part of the digestive tract for whatever food arrives. As soon as the food is digested the supply of enzymes is automatically switched off so that there is very little waste of precious materials. It is of course beyond the scope of this account to describe the control mechanisms. Suffice it to say that they are operated partly by nerve reflexes which signal the imminent arrival of food, and partly by special hormones produced in various parts of the gut wall. The best secretion is affected even by psychological factors so that pleasant company and surroundings attractive appearance of the food and an eager anticipation of it all make for good digestion and good health. These psychological factors are all capable of proper scientific investigation and proof. The poor health of those who habitually and irregularly bolt unpalatable food is probably due to such factors as these. So is the failure of appetite in the depressed the anxious adult or the scolded child.

Nearly all the digestion which has been described occurs in the stomach and upper part of the small intestine (the duodenum, jejunum, and upper ileum). Almost all absorption of the products of digestion occurs in the small intestine which is long and intricately folded to give it a large surface area for this purpose. The colon, or large intestine is adapted for conserving water by removing

it from the residual waste material. This has then to be eliminated and being rather dry its passage has to be lubricated by suitable secretions of mucus.

Constipation. Here perhaps we had better mention the morbid question of constipation about which so many people are obsessed and hold such pronounced views. First of all what is it? For some people it is entirely normal only to pass motions about once or twice a week. For others the normal frequency is once or twice a day. What is abnormal? The answer is that the only thing worth worrying about is any pronounced change of bowel habit particularly in middle aged and older people. By a change is meant a change from that individual person's normal routine. Such a pronounced change—either in the direction of constipation or diarrhoea is worth consulting your doctor about if it persists for more than a week or two. Otherwise forget your bowels and leave them to work naturally as they know best. Many believe that constipation is the root of all evil that it causes a mysterious condition known to them (although alas not to doctors) as auto intoxication. Sedulously fostered by the manufacturers of patent medicines their beliefs range from the notion that headaches, spotty skin, muddy skin and tiredness are caused by constipation to the more extreme idea that the whole system is being poisoned and that if the bowels do not work, the individual will shortly die. Of course all this is the merest rubbish for as Professor Samson Wright whose *Applied Physiology* is one of the most famous of medical text books has pointed out there is no such thing as absorption of poisonous products from the bowel. There is no such thing as auto intoxication. The symptoms of constipation he writes are largely due to distension and mechanical irritation of the rectum. It has been shown that an enema removes these symptoms immediately which would not be the case if they were due to poisons in the blood, and exactly the same symptoms can be produced by packing the rectum with cotton wool. Wright mentions the case of a man who went for just over a year without a bowel motion and at the end of that time although his abdomen was distended and he felt some discomfort he was not noticeably ill. Need less to say telling these facts to the purgative addict will only make him annoyed but it is as well to note that if no known diseases are due to constipation (although constipation may be a symptom of another disease) the regular use of purgatives can cause disease.

Constipation should be treated first by diet containing plenty of roughage—bran and oatmeal are excellent—plenty of stewed and fresh fruits and at least three pints of fluid should be taken daily. Failing that one of the best things to take is a proprietary product prepared from senna pods. Never to be taken regularly are liquid paraffin, castor oil preparations of aloes, Epsom salts and all the other dreadful stuff that people swallow down.

Esophagus

The esophagus or gullet is more than a simple tube for taking the food from the mouth to the stomach. It is normally closed except when swallowing and the act of swallowing is very complicated. When the material to be swallowed arrives in the back of the throat there is an automatic mechanism which opens the top end of the esophagus to receive it and from then onwards everything happens automatically. The next portion of the tube opens and the top closes strongly so that the food (or drink) is propelled forcibly down the next segment. Then the part below this relaxes and the material is squeezed further downwards and so on until it arrives in the stomach. This squeezing (or milking) action is akin to the action known as peristalsis which propels contents in other parts of the gut. Thus when you see someone swallowing a glass of beer very quickly in warm weather it is not going down the hatch under the influence of gravity however much it may look like it. It is perfectly

possible to swallow the same or any other liquid standing on your head. Getting into that position is the only difficult part. Sometimes this complicated swallowing mechanism gets out of order leading to difficulties of swallowing or *dyphagia*. Another disorder known as *hiatus hernia* occurs at the lower end of the oesophagus as it meets the stomach. At this point the oesophagus has to pass through the diaphragm the sheet of muscle which separates the chest from the abdomen. The muscular fibres of the diaphragm are normally arranged in a ring around the oesophagus. These help to keep the lower end shut so that the acid contents of the stomach do not regurgitate upwards causing inflammation (*oesophagitis*) or heartburn. A hiatus hernia is when muscle fibres get slack and the upper end of the stomach can even slide upwards into the chest. People with hiatus hernia get heartburn after meals and particularly when they bend down or lie down. Except for very severe forms which need surgical repair the treatment is to eat less at a time, reduce the acidity with a suitable antacid and reduce weight so that the weight of the abdomen does not press upwards so much. The other disease of the oesophagus quite unrelated to the above is *cancer of the oesophagus* the cause of which is still unknown in most cases. When cancer occurs in the wall of any tube it will often encircle the tube and gradually narrow the way through. This is what happens in the oesophagus leading to difficulty in swallowing particularly solids. It is a condition usually of rather elderly men although it is sometimes associated with a special form of severe anaemia in women. Treatment is in some way to keep the passage open either by transplanting a new tube or more usually by removing the constricted piece and joining up the remainder.

The Stomach and Duodenum

By far the commonest diseases of the stomach and duodenum are *peptic ulcer* and *duodenal ulcer*. They are actually the same condition in two different sites and are often classed together as *peptic ulcer* or *acid peptic disease*. The ulcers which are rather like sores on the lining of the stomach or duodenum may be acute or chronic. Acute ulcers tend to be small and there are often several of them. Chronic ulcers are usually single. They may be small or they may be several centimetres across. Chronic ulcers smoulder for months and even years like a sore which will not heal and a great deal of scar tissue forms in their depths. Thus they may in time erode their way right through the wall of the stomach destroying all its layers and begin to eat into surrounding structures like the pancreas or liver. The fact that they do not perforate more frequently is due to all the fibrous scar tissue which is formed during the slow eroding process. Healing of such a destructive ulcer is nevertheless common and the great problem is how to help the natural healing process to win against the ulcer's tendency to erode. Better still would be to discover the cause and prevent it happening in the first place. This extremely common affliction is confined to the human species and has been known since the earliest times. It does not vary very much with diet or with social class. Although occurring at all ages it usually begins between the ages of twenty and forty and is most commonly found in men between forty five and fifty five. Gastric ulcer is four times and duodenal ulcer ten times more common in men than in women. It is always due to an inability of the lining to stand up to the normal digestive activity of the stomach contents. These are normally acid and contain a powerful enzyme for digesting proteins. Again it is perhaps more surprising that we all do not digest our own stomachs rather than that some unfortunate people do digest small areas slowly. In certain abnormal conditions when the stomach stops making acid, ulcers always heal. However some ulcers occur without excessive secretion of acid and many heal without the acid being neutralised with antacids. All this points to the main trouble being in the response of the lining to acid rather than to the acid itself. Nevertheless the most effective treatment at present known involves regulating gastric secretion, and particularly its acidity. It is also known that peptic

ulcers are more common in people whose occupations involve administrative and professional responsibility, competitive effort and nervous tension, long periods of anxiety or frustration. Presumably the higher nervous system influences these events by the same nerves which normally help to control secretion.

The main symptom of peptic ulcer is pain and this usually responds well to proper doses of antacids. Many different varieties are available and a lot of money is made from selling them. When indigestion persists for longer than a few days it is always better to see your doctor so that a proper diagnosis can be made and the best remedies begun. Many other causes exist for similar pains and you should not try to make the diagnosis yourself. It may be necessary to analyse your gastric secretions in the hospital laboratory. Almost certainly you will have a special X ray examination, and since the stomach cannot easily be seen on a normal X ray they will have to show it up by making you drink a white material containing barium. This will be seen as a silhouette of the stomach and duodenal contents. Searching for an ulcer this way is a highly skilled matter and is performed by doctors specially trained in radiology.

Treatment of peptic ulcer is designed to relieve symptoms, heal the ulcer and prevent complications (see later). Some rest and sedation may help to deal with the psychological influences at work. A special diet may be required. If certain foods cause discomfort they will naturally be avoided but there is no evidence that any particular foods like coarse or highly seasoned things retard or that a soft bland diet enhances healing. The era of sloppy milky diets is almost over for which countless ulcer sufferers will be profoundly thankful. Suitable antacids will be prescribed. Once an ulcer is diagnosed the time has come to stop treating yourself with antacids from the shop chemist's counter and to take the case your doctor decides are best. Smoking should be stopped by ulcer patients (as indeed by everyone else but that is another matter) because it inhibits healing. Alcohol tends to increase acid secretion and should be avoided. It is also extremely important to avoid taking any form of aspirin even in quite small amounts since this can lead to very serious bleeding from the ulcer. The ulcer patient should be warned that hundreds of proprietary preparations contain aspirin and all of them are dangerous for him. Search for the name in small print on the label before taking any remedy, looking particularly for acetyl salicylic acid—the correct name for aspirin. Doctors have been pressing for years for a law which would make it obligatory for patent medicine manufacturers to label aspirin containing drugs clearly. There is still no such regulation, so that even some widely sold hangover remedies which are sold for upset stomachs contain large quantities of aspirin. Some of the patients with upset stomachs are of course ulcer patients and some even die of haemorrhage following the ingestion of aspirin.

The main complications of peptic ulcer are bleeding, perforation and a narrowing of the pylorus or lower part known as *pyloric stenosis*. Bleeding is caused by the eroding ulcer eating away at one of the many blood vessels in the stomach or duodenal wall. It leads to the passing of altered blood in the stool (*melæna*) or to the vomiting of blood (*haematemesis*). When the initial bleeding occurs the patient may feel suddenly faint and a little later will notice the black tarry colour of his stool. This is sometimes confused with a similar colour when the patient is taking iron. Peptic ulcer is not the only cause of this very serious hemorrhage, which constitutes a hospital emergency whatever its cause. The treatment like that of every large hemorrhage is blood transfusion which must be continued until the bleeding stops or until the patient is sufficiently fit for surgery should that be deemed necessary. Perforation is perhaps the most serious complication of peptic ulcer leading to the spilling of stomach contents within the abdominal cavity. Treatment is invariably surgical either

the closure of the perforation or the partial removal of the stomach

Surgical removal of part of the stomach is often the only way to treat a peptic ulcer which has had its chance to heal in other ways. It is tempting for the patient to have it out and done with but the time for surgery is a matter of fine judgment. So many ulcers heal by medical means if you give them a chance and operations are for those which persistently refuse or which become complicated.

Stomach Cancer The stomach is a fairly common site for primary cancer. There is no known reason for this and it is particularly important to stress that we know of no connection whatever between the peptic ulcers which have just been discussed and cancer. Stomach cancer used to be the commonest cancer of men but the current rise of lung cancer has pushed it into second place. There are some strange geographical differences in its distribution. For example it is much commoner in Japan and Scandinavia than in England or the U.S.A. It is difficult to see any reason for this in dietary habits. In Wales it causes three times as many deaths as in South-East England. All this is very puzzling as is much of our information about cancer generally. One of the main problems with stomach cancer is that it often causes the patient no inconvenience and thus produces no symptoms of note until the disease is far advanced and it is difficult to do much. Treatment is by surgical removal of the growth and even in the most advanced cases a great deal can often be done to make the patient more comfortable.

The Small Intestine

The small intestine runs from the stomach to the caecum and comprises the duodenum, jejunum and ileum in that order. On a more cheerful note it may be remarked that it is very rarely the site of cancer. Its main problems arise in connection with defects in absorption mechanisms with obstructions and with a strange inflammatory condition known as *regional enteritis*. Most obstructions are due not to blockages of the tube but to failures of peristaltic propulsion the process which is briefly described above under oesophagus. Such a failure is called *ileus*. When peristalsis stops for any reason, the result is severe dehydration and loss of important chemicals like sodium and chloride from the body. This is because about two gallons of fluid enter the small intestine each day in the form of digestive juices and all of this has to be pushed onwards to be reabsorbed into the system at lower levels. If peristalsis fails, this bulk of fluid remains in the small intestine or is vomited. In both cases it is lost to the body itself leading to serious dehydration and illness. Treatment is by very careful replacement by transfusion of the fluid and the chemicals lost and by removal of the trapped fluid within the intestine through a tube threaded down through the mouth.

Regional enteritis or *ileitis* is sometimes known as *Crohn's disease*. It is a very mysterious condition in which the normally supple wall of the small intestine becomes inflamed and gradually replaced by thick fibrous scar tissue so that it looks and feels like a thick garden hose. Loops of inflamed gut stick together and channels open between them and if the disease progresses a mass of adherent thickened intestine results to which everything in the neighbourhood also adheres. However for some unknown reason some cases do not progress downhill in this way and get better spontaneously. Surgical treatment is necessary for the majority however, particularly those with advanced disease leading to complications such as obstruction or perforation. Sometimes an early case can be resolved by cutting out the length of affected gut although recurrences are unfortunately common.

Appendicitis This must be one of the best known surgical diseases of the intestinal tract.

The appendix is a narrow blind-ended side tube attached to the caecum near the end of the small intestine. Appendicitis is when it becomes obstructed or infected or both. From its position it is almost predictable that it will get obstructed sooner or later by pieces of faecal matter which pass its entrance and which are normally infected. The surprising thing is that it does not happen more often. Once this has occurred however a closed abscess forms and as the abscess distends the appendix it first weakens its wall making it gangrenous and then bursts into the abdominal cavity causing *peritonitis* (see later). It would be useless and misleading to describe the symptoms of acute appendicitis in detail since it is difficult even for experienced doctors to distinguish them from those of several other conditions. Suffice it to say that any severe persisting pain in the abdomen whether continuous or intermittent whether associated with diarrhoea or not should lead the sufferer to a doctor for a quick diagnosis. Germ-killing antibiotics are useless against appendicitis and any laxative is extremely dangerous as it may cause an acutely inflamed appendix to perforate.

The Large Intestine or Colon

The two main serious diseases of the colon are ulcerative colitis and cancer in its various forms. *Ulcerative colitis* is yet another mysterious disease in which severe ulceration of the lining of the colon gives rise most frequently to diarrhoea with the passage of blood and mucus. In fact it can be like dysentery and it has often been considered to be due to some form of infection. Unfortunately no particular germ can routinely be found in these cases and the situation is endlessly confused by the presence in the normal bowel of lots of different germs anyway. Nevertheless the ulcerated lining of the bowel certainly does get infected by the germs normally present and this makes the disease worse. Therefore germ-killing antibiotics are often helpful in alleviating symptoms and can lead to an earlier settling down of the condition, although not to a cure. It has long been known that certain kinds of psychological upset are often associated, but here again the disease is so unpleasant for the sufferer that he is to be forgiven some despondency as a result of rather than as a cause of his troubles. It is also suspected that ulcerative colitis may be an auto-immune disease, that is it may represent rejection by the patient of his own colonic lining in a manner somewhat comparable to the tissue rejection which often follows organ transplantation. Some of the more alarming complications are perforation through the wall of the ulcerated bowel and sometimes massive haemorrhage occurs. Medical treatment takes the form of keeping the patient in good physical condition in spite of his fluid and blood loss and his frequent lack of appetite. Surgery is often required to relieve obstruction, deal with perforation, remove chronically affected parts of the bowel etc.

Cancer of the Colon and Rectum This is another very common form of cancer which can often be completely cured by surgical removal of the growth provided it is caught in the early stages before it has spread. The commonest symptom is a change in bowel habit either towards constipation or more often towards diarrhoea in the second half of life. There may be rectal bleeding or the passage of mucus and there may be abdominal pain. We cannot too often repeat that any such change of bowel habit, or any unexplained bleeding from any site should lead the patient promptly to his doctor.

Diverticulitis Some people have small pockets or sacs in the wall of the colon known as diverticula. A minority of these sometimes get inflamed and this is *diverticulitis*. Occasionally perforation occurs.

Hernia or Rupture This is a condition in which abdominal contents, usually a loop of intestine protrude forwards through the muscular

wall of the abdomen. The wall consists of a sheet of muscle fibres running in several directions. They normally become tense when we cough or strain or in getting up from a recumbent position. There are places in the groin on each side where there is a way through the muscle for the spermatic cord in the male. In many men a weakness can arise at this point and if it persists the way through may enlarge and allow loops of bowel to emerge from behind the muscle sheet to appear as a lump under the skin of the groin. On relaxation the lump can be made to disappear by pushing the contents back the way they came and they will re-emerge when the patient strains. This is an extremely common complaint in men and it should be treated by an operation in which the muscle wall is repaired. Some men however neglect to have their rupture treated until one day it proceeds to strangulate. This is the term used when the muscle tightens around the neck of the protruding loop of bowel cutting off its blood supply. From then onwards the loop becomes gangrenous and the intestine is obstructed by having a part of itself ripped outside the abdominal wall. The patient is in severe pain vomits continuously and quickly is liable to get into such a poor condition that surgical relief is difficult. It is therefore a surgical emergency and it would have been better to have had the relatively simple repair operation earlier and at leisure. Hernia in the region of the groin is of two types *inguinal hernia* and *femoral hernia* the difference between them being technical and of no consequence to the patient. They nearly always occur in men. Other types of hernia less frequently occur in both sexes. *Incisional hernia* is when the muscle wall has been weakened at the site of an old abdominal operation and has failed to heal properly. *Umbilical hernia* occurs owing to the natural weakness of the abdominal wall at the navel and is so common in babies as to be almost normal. When a baby cries and thereby puts a strain on his abdominal wall a lump often appears in the region of the navel and this can be very alarming for the parents. They should of course show it to their doctor who will nearly always be able to reassure them. It is self healing without operation in the majority of cases.

Peritonitis. The cavity of the abdomen in which the intestines and other organs lie is called the peritoneal cavity and it is lined by a thin membrane called the peritoneum. When this becomes inflamed the condition is serious one and is called *peritonitis*. Inflammation may be bacterial as occurs following a burst appendix and the spillage of bacteria and pus in the cavity. It may be a sterile peritonitis as often follows perforation of a peptic ulcer when the inflammation is caused by the acid contents of the stomach. It is always very dangerous probably because of the large surface area afforded by the peritoneum for the absorption of inflammatory toxins.

Hæmorrhoids are simply varicose veins in the rectal and anal regions. They are very common and are caused probably in about equal degrees by inherited weakness of the veins strain such as heavy lifting and constipation (this is one of the very few conditions in which constipation may do some damage due to the mechanical pressure of hardened feces in the rectum on the veins). Pregnant women are liable to develop hæmorrhoids or *piles* as they are commonly called owing to the pressure of the baby's head in the pelvis. Hæmorrhoids may be external or internal the former being in the anal region below the sphincter the latter in the rectum the two usually go together. There may be no symptoms but the veins are liable to bleed to get thrombosed (i.e. a clot forms within) or to become infected. When clotting or infection occurs the piles enlarge and tend to be pushed out through the anus during defecation when they form extremely painful external swellings. Treatment in simple cases may be by the use of suppositories—cones of a firm grease containing suitable medicaments which are inserted in the rectum—in other cases the veins may be injected as with varicose veins of the leg in order to close them, but when there is

much bleeding thrombosis infection or interference with bowel movement they should be removed surgically.

DISEASES OF THE LIVER

The liver is the largest organ and has such a wide variety of known functions (to say nothing of the unknown) that it is also one of the most complicated. Nearly all of its functions are biochemical and it is often called the laboratory of the body. Medical students when asked to enumerate the functions of the liver usually stick at about twenty five nearly all of them to do with general metabolism that is the biochemical processing of substances taking part in structure or as body fuel. For example the liver makes proteins from the amino acids absorbed from the gut and breaks down amino acids and manufactures a waste product (urea) from them. It stores carbohydrates as glycogen and conducts many of the processes necessary to turn carbohydrates into energy. It manufactures prothrombin with the help of vitamin K and this is essential for blood clotting. It makes bile and secretes it into the gall bladder and bile ducts (see later). The three main constituents of bile (cholesterol bile pigment or bilirubin and bile acids) all have to be processed or metabolised in the liver during the production of bile. Vitamin B₁₂ and iron is also stored and dealt with there and these are involved in preventing various forms of anaemia (q.v.) and in addition to all these things the liver is the place where harmful substances both from within the body and from outside it are dealt with and rendered harmless. This last function of detoxication is often accomplished by making the offending molecules suitable for rapid excretion by the kidneys or by altering their chemical shape to make them harmless.

Nearly all of these very different things are done by one single type of cell the liver cell and it is one of the remarkable features of the design that this cell can be so versatile. There also have to be some very efficient transport systems in the liver in addition to the usual blood supply and venous drainage possessed by all other tissues.

One of these is the portal venous system. Whenever a substance is absorbed across the gut wall from any part of the intestine into the interior of the body it enters the special draining blood vessels of the portal system which are arranged throughout the length of the digestive tract. All these veins eventually unite in the main portal vein which enters the liver. Everything absorbed from the gut is therefore taken first to the liver to be processed. After this the products are carried away from the liver in the ordinary veins to the heart and are distributed to the rest of the body by the arterial system. The liver has arteries of its own by which it receives oxygen and nutriment like any other tissue. The fourth transport system collects the bile as it is formed within the liver and delivers it to the gall bladder and bile ducts which eventually drain it into the duodenum.

Portal Hypertension means high blood pressure in the portal venous system and is the usual accompaniment to *cirrhosis* (see later). When the terminations of the portal veins in the liver are strangled and obstructed by cirrhotic disease this tends to blow them up or dilate them with blood. There is a natural escape route for the portal blood where the lower end of the oesophagus or gullet joins the upper end of the stomach. At this place some of the portal veins draining the stomach are connected with the ordinary veins draining the oesophagus so that when pressure rises in the portal system, blood tends to be diverted into these connecting veins and they in turn become dilated or varicose. Trouble begins when these dilated connecting veins which bulge inwards into the oesophagus are damaged by food particles passing across them and bleed severely into the stomach. The patient vomits large quantities of blood (*haema temesis*) or passes tarry altered blood in the stool.

(*melæna*) The other main cause of these is the bleeding which occasionally accompanies peptic ulcer (*q v*)

A second complication of portal hypertension (and hence of cirrhosis) is *ascites* in which large amounts of a lymph like fluid accumulate in the abdominal cavity. The fluid contains a great deal of precious protein and salt which is lost to the body economy. *Ascites* also sometimes accompanies cancerous deposits in the abdomen.

Jaundice means being yellow because there is too much yellow bile pigment circulating in the blood and there are three main possible causes for this. The term yellow jaundice like gastric stomach is therefore unnecessarily redundant there is no other kind.

Bile pigment comes from broken down red blood cells which normally come to the end of their time after existing for about 120 days. The breakdown products of red cells can always be found in the blood of normal people but there is normally insufficient colour to show. Abnormal amounts of colour build up quite logically in any of the following three circumstances

(1) If too many red cells are being destroyed and even the normal liver cannot deal with the amount of bile pigment produced it piles up in the blood and *haemolytic jaundice* is the result. The expression simply means jaundice due to (abnormally large) red cell destruction.

(2) If the liver cells are themselves sick and unable to cope even with the normal amounts of pigment from normal red cell destruction. Here too the pigment will pile up and cause *hepatocellular jaundice* or liver cell jaundice.

(3) If the bile ducts carrying bile away from the liver are blocked, then bile will pile up behind the blockage and re enter the blood stream causing *obstructive jaundice*. In this case the rate of red cell breakdown is normal and the liver cells are normal at least for a time.

It is enormously important for the treatment of jaundice for the doctor to diagnose its type correctly since the treatment varies from surgical relief of obstruction to the medical treatment of viral infection or of excess red cell destruction.

The so called differential diagnosis of jaundice is often exceptionally difficult and sometimes requires some very sophisticated laboratory tests and X rays. At other times it is extremely easy and is obvious from a cursory glance at the urine and the stool. In any case all jaundice is a highly technical matter for the doctor who must be consulted early.

There is a special jaundice of newborn babies which resembles haemolytic jaundice and can occasionally have serious consequences for the developing brain (*kernicterus*) if it is allowed to become too severe. When this is threatened steps are taken to reduce the level of circulating bile pigment by replacement of the baby's blood or by other means.

The commonest cause of hepatocellular jaundice is infective or viral hepatitis. Obstructive jaundice is usually due either to blockage by gallstones (*q v*) or by a lump pressing on the bile ducts from an adjacent cancer. This can often be quite satisfactorily relieved by surgery.

Infective Hepatitis There is a group of disorders affecting the liver which are caused by viruses. The incubation period is often very long and the sickness and other debility caused is often quite severe and prolonged. One variety known as serum sickness is now much less common than a few years ago. It used to be transmitted by using the same needle for injections into several different people or from transfusing contaminated blood. A greater awareness of the problem and the use of disposable needles and syringes has cut down the incidence.

Cirrhosis There are many different kinds of cirrhosis the commonest of which has already

been mentioned under *portal hypertension* above. In all cases liver cells are slowly poisoned and are killed off over a long period of time. In response to this the surviving liver cells undergo cell division trying to make good the numbers lost and at the same time fibrous scar tissue replaces the damaged tissue throughout the organ. The result is a hard knobby liver. The many

knobs are spherical areas of regenerated new cells and they are separated by thickened bands of scar tissue. All of this destroys the normal architecture and leads to the portal hypertension and *ascites* mentioned above. In some countries (*e.g.* France and the United States) excessive alcohol is the main cause of the original liver damage which starts it all off. In others (*e.g.* Bantu South Africa) it seems to be nutritional starvation of the liver. In England much less than half the cases are due to alcohol and many are thought to be due to a previous episode of infective hepatitis (*q v*) but this is not certain. Infective hepatitis is quite common but cirrhosis is comparatively rare. So that the great majority of people do not progress from one to the other. One day soon the treatment for advanced cirrhosis will be to replace the liver by transplantation but there are still many problems to overcome before this can become routine.

Cancer of the Liver Cancer of the liver is quite common but it is nearly always cancer which has spread in the blood stream from other parts of the body. The liver is a favourite site for such secondary deposits since it has a large blood supply and will receive a generous helping of anything being carried. It is also a very fertile soil for the cancer seedlings to grow in. Primary cancer of the liver is uncommon and only occurs in a few cases of pre-existing cirrhosis.

Gallstones These are stones formed by some of the major constituents of bile coming out of solution and forming solid bodies. They are very common and often cause no trouble at all. When they do it is usually a cholelith in intermittent severe pain. This is due to the muscular walls of the bile passages contracting in an effort to expel an obstructing stone into the duodenum. The second common trouble arising from gallstones is obstructive jaundice described above. It is small consolation to gallstone sufferers that the stones are often very pretty often being composed of beautiful cholesterol crystals coloured by varying shades of bile. If they contain calcium they will be visible on an X ray. Otherwise they are not seen. There is a persisting myth in the textbooks that sufferers are usually females who are Fair Fat Forty and Fecund. It is not true. Stones often occur in conjunction with inflammation of the gall bladder known as *cholecystitis*. The treatment for gallstones is to remove them surgically together with the gall bladder if they are causing persistent symptoms.

The Pancreas.

This is a soft elongated gland lying behind the stomach. It is about 5 in. long and 2 in. wide. Within its tissues lies the duct which when it leaves the pancreas passes into the duodenum near the point of entry of the bile-duct. This duct transmits the juices containing enzymes which aid in the digestion in the small intestine. The pancreas however has two main functions not only does it manufacture these important digestive juices but in certain specialised areas known as the islets of Langerhans it manufactures insulin the hormone which makes it possible for the body to utilise sugar. *Diabetes mellitus* or ordinary diabetes is a chronic disorder usually caused by a deficient secretion of insulin. The unused sugar accumulates in the blood and acts as a poison which in extreme cases sends the patient into coma and may—indeed in former times usually did—result in death. The treatment of diabetes was revolutionised by the discovery of the hormone insulin by Banting and Best in 1921. On the whole diabetes is more severe in young people than in the elderly but with correct treatment it is possible for all cases to lead a perfectly normal life except for dietary restrictions and insulin injections. Not to be confused with *Diabetes insipidus* (F45(2)).

DIET

When considering diet and the effect it has on our health and well being, there is more to it than just the things we eat. We must also know about what our body does with the food, and it would be unscientific not to acknowledge the effects of our psychological make up and our nutritional beliefs on what we eat, what we do with it, and how well (or ill) we feel as a result.

For example, a deep rooted conviction that brown eggs or free range poultry are better for us than white eggs or intensively reared birds is entirely unsupported by any evidence. However, if we believe such a thing sufficiently we will not only eat the better ones but we will feel happier and more secure afterwards and this is likely to make us healthier. Food fads can occasionally be dangerous as when extreme vegetarians become ill through lack of certain vitamins (e.g. B₁₂) which are present only in the foods they exclude. But this is so rare even among strict vegetarians that such danger can virtually be ignored. On the whole and vegetarianism is probably a good example of this) food faddism often leads to a sense of health and well being in the believer and should not be attacked by the rest of us for that. It is an accepted fact that personal misfortune even when it is severe is more easily withstood by those with strong religious conviction than by others. In the same way a firm attachment to a theory of what is good for you can produce a feeling of well being and genuine good health when another person on exactly the same food intake will not feel so fit. These factors—religious belief, food faddism or the bedside manner of a kind or persuasive doctor—are commonly dismissed by free thinking people because they are not true or real. All three however can materially affect our health just as can a shock, a personal tragedy or being in love. The trouble starts and the magic ceases to work when adherents declaim their beliefs as *ex cathedra* truths and expect the rest of us to swallow them as wholly (or holy) as they do.

Thus there are genuine facts about food and fallacies too, and as well as these there is a no man's land between in which one man's fact is another man's fallacy.

The basic constituents of any diet are protein, fats, carbohydrates, water, vitamins, minerals, salts and indigestible roughage. All are chemicals whose structure and function are reasonably well understood. Even the mystical differences between fine table wines so beloved of the connoisseur and gourmet are reasonably well understood in chemical terms. Perhaps that is a pity.

Much nonsense is talked, especially by nutritionists about minimal daily requirements. In general terms, however, requirements can be described in terms of how many calories there are in the total intake of proteins, fats and carbohydrates per day and how these are distributed between the three classes of food. The other substances mentioned above are only required in trace or small amounts except for water and roughage is only required as a mechanical stimulus to bowel movement.

During the process of digestion (described on P34-5) all proteins are split into their constituent amino acids, all carbohydrates are split into their constituent simple sugars and most fats are converted into fatty acids and glycerol. At this stage and not until this stage all these simpler building bricks derived from the three classes of food are absorbed into the body proper and taken to the liver and other tissues. Here they are "metabolised". That is to say they are either burned as fuel for the various processes of the body or they are built up again into proteins, fats and carbohydrates of the special kinds the body needs. They will either be used to rebuild structures suffering ordinary wear and tear or they will be stored. Many of them will be converted into a different class from the one they came from when they entered the body. For example, excess carbohydrate is converted into fat or if there is a shortage of carbohydrate some will be made out of the protein amino-acids which would normally have been used for tissue growth and repair. Thus it is only a generalisation to say that dietary carbohydrates are fuel and proteins are for building bodily structure. The body can convert

one into the other and spoil the calculation.

There is a great deal of confusion in people's minds about *energy* and that is why the word *fuel* has been used above in connection with carbohydrates. The lay person uses energy as a term meaning something which allows us to leap about, running and jumping and skipping and dancing and which keeps us from getting tired and run down. Thus the food industry tells us we need potatoes or breakfast cereals for these activities or for a hard day's work. This is a deliberate commercial confidence trick and the scientist is largely to blame. He originally handed out the word energy to an eager food industry and an unsuspecting public forgetting to explain that he meant it in the strictly scientific sense of fuel for bodily processes. It simply is not true that more potatoes or more cornflakes will make you more active. Indeed the reverse is the case and after a certain point they will only be converted into fat and reduce your activity. The nutritionist measures energy as calories which are units of heat and it is certainly true that you must eat enough of these each day if you wish to remain alive let alone active.

All the three main classes of food provide calories and in an ordinary well balanced diet about 15% are provided by protein. Carbohydrates produce most of the remainder. Each gram of fat contains about twice the calories of a similar quantity of carbohydrate. We simply eat less fat than carbohydrate because fat has a high satiety value. It takes away the appetite for more. Proteins are mostly found in meat, fish, eggs, cheese and milk. However there is quite a lot of protein in many predominantly starchy foods like bread and such grains as wheat, rice and corn. Carbohydrates are mainly found in bread, potatoes, sugar, pastry, sweets, and so forth. That is one of the words which fortunately seems to be used by both scientists and laymen in much the same sense.

Some substances are absolutely essential to the body if life is to continue even if they are only needed in trace amounts. These are substances which the body's own factories (like the liver) cannot make for themselves even if they are provided with the correct ingredients. Unfortunately these essential constituents were given a system of names which grew like Topsy as they were discovered and which have led due to common usage even though more recent knowledge has made a nonsense of most of the words. One whole group of such substances is the *vitamins*. All of these by definition are essential and have to be provided for the body in the diet. Vitamins are another gold mine for the food and pharmaceutical industry. The public know that scientists have discovered these magic substances only in tiny amounts of which are required to keep people healthy. Starting with that piece of magic it is not difficult to mislead people into two sorts of erroneous conclusion. The first is that all signs of minor ill health and tiredness (from which we all suffer at times) are due to lack of these vitamins and secondly that extra vitamins are the key to extra health. The truth is that no one in England who is eating a normal diet is short of vitamins in it and there are no dividends in extra health for taking vitamins above the normal daily intake present in food. It simply is not true that extra vitamin C or D gives protection from colds and other winter ailments. The fate of the extra vitamin intake however expensive is the same as the fate of anything else the body cannot use: it finds its way expensively into the lavatory. The money would have been much better spent on wholesome meat or other non fattening food.

Thankfully most people buy food because they like it not because it does them good and provided they have normal dietary tastes they will usually get a perfectly adequate selection of the things we have spoken of as necessary for good health. The main danger in England is to have a surfeit and become overweight. In addition there are certain times of life when conscious attention should be paid to what is necessary. For example babies and nursing mothers have special dietary needs and will hear about them from their Health Visitor or from their Welfare Clinic or Doctor. Elderly people living alone are also prone to dietary deficiencies for reasons

ranging from poverty to loss of appetite or in ability to look after themselves properly.

Recent surveys have revealed some interesting facts about people's attitude to food and their knowledge of it. For example half the people asked knew that meat was a source of protein, a third mentioned eggs and a fifth cheese, fish and milk. But practically no one knew there was protein in bread. Yet in England about a fifth of our daily protein intake comes from bread and nearly a third from cereals as a whole. Fish is well known as a source of protein, but did you know that on average we only obtain 4% of our daily protein from fish—less than we get from potatoes (5%)? No one seems to know that potatoes are an important source of vitamin C although fruit and vegetables are well known sources. Calcium is recognised in milk, but most people forget its presence in cheese. Most people are very confused about iron. Why does everyone think it is mainly in green vegetables when these are really such a poor source? Are we indoctrinated by Popeye? For our daily requirement of iron we would each have to eat 2½ lb. spring greens or peas or 4½ lb. of sprouts! In fact meat provides one of our best sources and one fifth of our daily needs is contained in bread.

Since most of the people who read *Pears* live in England let us return finally to our commonest nutritional disease or our commonest form of malnutrition in these islands: obesity. Call it being overweight if you like but acknowledge that it means being fat. Being fat is not only unattractive and unsightly but it is dangerous to health and carries a high mortality. Ask any life insurance company how they view your chances if you are overweight and you will find they are as worried about it as if you had high blood pressure or smoke heavily. It is a particularly important cause of heart disease. However it is very important to know exactly what we mean by fatness. Many girls who are not at all fat think they are and this leads them to diet unnecessarily. On the other hand there are people who do not appreciate they are overweight. Here is a table which shows what your weight should be according to your height.

If you are overweight according to these tables you need to slim and the question is how? Answer by will power. There is no other satisfactory method than to decide to eat less and to eat as little carbohydrate as possible. For the time being eat as much meat, fruit, green vegetables and as much fat as you like, but no sugar, starch, sweets, cakes, pastry or biscuits and no eating between meals. And cut down on beer and other alcoholic drinks. In case you are tempted to eat slimming foods be aware that there is no such thing. There is nothing you can eat which will cause you to lose weight in spite of what the advertisement says. In special cases doctors will prescribe tablets to suppress appetite but they

DESIRABLE WEIGHTS FOR MEN AND WOMEN ACCORDING TO HEIGHT AND FRAME AGES 25 AND OVER

Men Height (with shoes on— one inch heels)	Weight in pounds (in indoor clothing)

are too dangerous for general use without supervision and they do not work as well as will power. At the same time take more exercise. Walk to work. If you make a real and genuine effort for three months without success you should ask your doctor for advice. Almost certainly you will have to admit you have not really tried. Good luck!

NUTRITIONAL DISORDERS

Nutritional Deficiency and Malnutrition—Until quite recently a consideration of malnutrition would have merely led to an account of how too little food or a deficiency of certain articles in the diet produced deficiency diseases at the time of the restriction. For example lack of vitamins of various kinds gives rise to such diseases as rickets, scurvy, beri beri and pellagra, and an overall shortage of food to general starvation. These may be considered the immediate or concurrent effects of a poor diet. Modern nutritionists, however, are beginning to be concerned with two more kinds of nutritional disorders and although the study of both kinds is in its infancy, both will be introduced in this account.

The first deals with the effects of comparatively small amounts of harmful constituents in our diet introduced either voluntarily or involuntarily and consumed for a long period of time, and the second with the lasting effects on our adult well-being of nutritional deficiencies in early life even though they have long since been corrected.

When viewed in this light, one or other of these three kinds of nutritional disorder may at this moment be affecting almost every individual in every part of the world, privileged or underprivileged. Let us first define some terms.

Undernutrition strictly speaking means a state of affairs in which the quality of the diet is perfectly good. There is the correct balance of the various dietary constituents and all the necessary components are present, but there is simply too little of it. Many hundreds of millions of people throughout the underprivileged world are suffering and dying from this kind of undernutrition, and the simplicity of the problem must be appreciated: they simply need more food of the kind they are at present getting and which can often be produced locally.

Malnutrition means an imbalance of the various constituents: a relative lack or excess of one or more of them. It usually leads to conditions which are from the point of view of medical treatment much more difficult to deal with. And therefore doctors often class them as more serious.

The diseases of malnutrition range from the widespread protein deficiencies in other parts of the underprivileged world to *obesity* in our own better off industrial countries, which is usually due to excess carbohydrate. Make no mistake about it: obesity (or being overweight) is a wide-spread disease of nutritional imbalance and it kills. It is the commonest form of malnutrition in (for example) England and America today and is a consequence of the sophistication of our diet in modern times. Between one fifth and one

tenth of the population of the United States is more than 20% overweight and to be 10% or 15% overweight is almost the rule nowadays in people over thirty. There are high authorities in the world of nutritional science who attribute all this overfed malnutrition to the consumption of refined sugar or sucrose. They say it is not only the amount of refined sugar we put in our tea or on our breakfast cereals but also the amount in sweet cakes biscuits drinks chocolates and sweets and so forth. For some people it adds up to a phenomenal quantity each day. According to this school of thought we are no so much suffering from a surfeit of carbohydrates or starches but from this single sugar sucrose. It is interesting to reflect on the recent banning of the artificial sweetener cyclamate by many governments. This substance having been used extensively throughout the world as an apparently harmless non fattening substitute for sugar was suddenly banned in America because in very large doses (equivalent to the amount taken in hundreds of cups of coffee per day for a long time) it was found to produce cancer in rats. It has never been shown to do humans any harm whereas the effects of sugar in producing an overweight population thereby indirectly kill tens of thousands of British people each year. This is a fascinating example of the difficulties confronting our legislators in making balanced judgments when deciding to ban a foodstuff a drug or an artificial fertiliser.

Much the most widespread form of malnutrition however is a variety protein lack which is part of a collection of nutritional diseases known as *Protein Calorie Deficiency*. In very large underprivileged areas of the world the childhood population receives such an inadequate diet that children live continuously on the brink of nutritional disaster. It only requires a small extra restriction or stress to topple them over into one of the clinical conditions to be described. At this stage they cease to be merely hungry. They become nutritionally ill. Sometimes the force which produces the disaster is a community catastrophe like a famine or earthquake or a war. Sometimes it is a family catastrophe like the loss of a lactating mother or a parental delinquency. Parents abandon young children as often in Africa as anywhere else. Sometimes the clinical nutritional disease is unmasked by a common childhood illness like measles or gastro enteritis which the well fed child would have overcome. The starved child reveals his malnutrition instead and frequently dies. When the precipitating cause of the epidemic of malnutrition is a war or other national calamity our newspapers and television screens carry distressing pictures of thin skeletal pot bellied children and the conscience of a few is touched. It is insufficiently realised that these scenes can be witnessed anywhere in the continents of Africa and Asia and in large parts of Central and South America any day of the week in normal times. The war has not been the cause but is only the precipitating factor which has revealed the chronic malnutrition in more children than would normally exhibit it openly.

Protein Calorie Deficiency is a collection of different kinds of childhood malnutrition. Some are due predominantly to deficiency of protein and are collectively called Kwashiorkor a West African word meaning red haired boy (see below). Others are mainly due to a severe deficiency of overall foodstuffs and are called Marasmus. But in any real life situation the severe malnutrition of Kwashiorkor exists side by side with all gradations between itself and the severe undernutrition of Marasmus so that many intermediate forms of marasmic kwashiorkor are described. In kwashiorkor the child is typically listless apathetic whining with a reddish discoloration of the hair a peeling scaly skin and with much extra fluid in his tissues causing oedema. He is so listless as not even to be hungry. In marasmus the child is ravenously hungry. He is extremely thin and starved looking and is quite a different picture.

There is good reason to believe that even when protein-calorie deficiency is successfully treated there will always be some lasting restriction of mental function particularly if the malnutrition

occurred as early as the first year of life. This is especially true in situations of appalling poverty in towns where thousands of babies are not breast fed because their mothers are at work. Many of them die. Some of them are no heavier than their birth weight at one year of age. Breast feeding in an underprivileged community is an essential insurance for childhood health and survival.

Two new avenues of nutritional inquiry were mentioned at the beginning of this section. The impact of very long continued intake of refined sugar over many years on our bodily health is an example of one of them. Scientists and others are also becoming alarmed at the effects of modern food additives when taken even in small amounts over a long period. These additives include colouring matter decolourising chemicals taste enhancers and so forth which are present in everyone's diet in a civilised community. We are unable to avoid a constant dosage with them as if they had been added to our water supply. It is however difficult to strike a balanced attitude. It is one thing to suspect that these additives are harmful and quite another to prove it. Naturally if any of them are shown to produce harm in animals given reasonable quantities they are invariably withdrawn. But in practice it is extremely difficult for animal experiments to mimic the conditions of human intake especially as the human life span involves eating the substance concerned in small quantities for several decades. Thus it is easy to postulate the harmful effects of monosodium glutamate (a very common taste enhancer) but practically impossible to prove the question either way. It is not sufficient to condemn chemicals. All natural foods consist of chemicals and so do we.

The other new topic in nutrition is more soundly based on animal experiment. It has been repeatedly found that if animals do not grow quickly enough at certain early periods of life they not only become small but they remain smaller than they should be even when they are subsequently given as much as they like to eat. This is true of all animals and birds so far studied. For example if rats are suckled in large families it is found that they are smaller by the time they are weaned (3 weeks of age) than those suckled in small families. The interesting thing is that if they are then given as much as they want to eat for the rest of their lives the small animals from the larger families never catch up to the others. Whereas if their growth is not restricted until later in their childhood full catch up is possible soon after normal diet is resumed. In other words there is a critical time in early life when growth can be permanently affected. At the moment it is difficult to know whether the same is true of humans and if so when is our period of vulnerability. There is some suggestion that the corresponding critical period in humans is during the last part of gestation in the uterus and the first year or so of postnatal life. This new idea may turn out to be very important for world nutrition. Since there will not be enough food for all the children all the time it may become important to concentrate our aid to underprivileged countries on certain sections of the population only. It may be a good idea to see that pregnant mothers and small babies are specially fed. In this way we may be able to put off the periods of inevitable malnutrition until a time of life when it is recoverable. Such a plan would also go a long way to safeguarding the development of the brain which also occurs mostly at the same early time of life.

We shall now describe some of the better known nutritional deficiencies beyond in mind that vitamin deficiencies are virtually unknown in the better off countries. No one in England need spend money buying vitamins as has been emphasised in the preceding section. Vitamin deficiency can still occur however in elderly people living alone and not having a well balanced diet. It also occurs for similar reasons in alcoholics vagrants etc. and very occasionally in small children.

Beri beri is a group of diseases usually confined to the Far East where a diet of polished rice results in a poor intake of vitamin B₁ (thiamine). In one form there is oedema (*q.v.*) in another the peripheral nerves are affected leading to tingling

and numbness. A similar condition is occasionally seen in alcoholics and diabetics. Treatment is with thiamine and with other vitamins too since most sufferers are going short of more than one.

Pellagra is found among maize eating populations and is due to a deficiency of several vitamins including niacin, another member of the B group of vitamins. There is dermatitis on exposed skin and soreness of the mouth and tongue with gastro enteritis.

Scurvy is due to vitamin C deficiency. In children bone growth is affected. At all ages there is bleeding into the skin (bruising), impaired wound healing, mental depression and anaemia. Most fresh fruit and vegetables contain vitamin C and a diet containing these prevents the disease.

Vitamin A deficiency is commonly found in children in some underprivileged countries. It causes permanent blindness with thickening, opacity and dryness of the whites of the eyes leading to ulceration of the eye. Beyond a certain stage therefore a child's sight cannot be saved. The only real hope is prevention with an adequate diet.

Rickets, another disease of early childhood is caused by deficiency of vitamin D. Bones are not properly calcified and their softness leads to deformities of the legs and many other bones. Vitamin D can either be eaten in the diet or produced under the skin under the influence of sun light. Therefore rickets commonly occurs when both the diet and the sunlight are inadequate. It was once very common in industrial England and is still to be seen very occasionally there and in impoverished urban communities in the United States.

DISEASES OF THE ENDOCRINE GLANDS.

Glands are structures or organs which manufacture secretions (except for *lymph glands* which are not glands at all and should be called *lymph nodes*). The secretions are of two main kinds. The first are passed down tubes or ducts or are secreted directly into the hollow organs and act locally. Good examples are the salivary glands which make saliva and pass it down ducts into the mouth for digestion of its contents and lubrication. These are *exocrine glands*. The second kind have no ducts and secrete their product straight into the blood stream. This secretion is called a *hormone* and it is carried to all parts of the body by the blood where it acts at a distance on some remote part. These are the *endocrine glands* or *ductless glands* and a number of them will be discussed in this section.

The first hormone or chemical messenger was discovered by the British physiologist Starling in 1904 but the effects of removing some of the endocrine glands were known centuries before when removal of the male testes (castration) was practised to procure a form of manpower safe for the harem to salvage a good male alto voice for the church choir or to convert a rooster into a more eatable capon.

Anterior Pituitary—Many of the endocrine glands do not act as separate autonomous organs in spite of their great differences. They are organised into a well disciplined band by a master gland called the anterior pituitary. Somebody once called it the conductor of the endocrine orchestra and the phrase is still repeated *ad nauseum* in students' examination papers. The pituitary consisting of its two parts, anterior and posterior is not much bigger than a pea and it sits right in the middle of the skull centrally beneath the brain and joined to the brain by a short stalk. This astonishing tiny nodule of tissue produces at least eight important hormones.

One of these is *growth hormone* which is necessary for normal growth and also has an influence on insulin. An excess causes *gigantism* and *acromegaly* often coinciding with diabetes and

too little results in a form of dwarfism. Three others known as *gonadotrophic hormones* regulate the cyclical and other activities of the reproductive organs and lactating breast. Another *thyrotrophic hormone* regulates thyroid activity. *Adrenocorticotrophic hormone* or *ACTH*, as its name implies looks after the activities of another important endocrine gland the adrenal cortex. And there are several others.

Hypopituitarism including *Simmonds' disease* and *Sheehan's disease* results from destruction of the anterior pituitary. It is extremely rare and is usually associated with difficult childbirth involving very severe bleeding. There are disturbances of all the functions mentioned above particularly thyroid and adrenal failure (*goitre*) with upset sexual function. Treatment is by replacing the lost hormone.

Hyperpituitarism including *gigantism* and *acromegaly* results from overactivity of the anterior pituitary and is usually due to a tumour or overgrowth of the gland. In acromegaly the growth hormone is produced in excess over a long period of time in an adult. This results in overgrowth of all the organs except the brain and it is characteristic to find enlarged extremities—feet, hands and jaw. In gigantism the same has occurred during childhood before the bones have stopped growing and the result is a person who may be 6 ft 6 in. tall or more.

Posterior Pituitary The posterior part of the gland is really a quite separate gland. The main hormone it produces is concerned with the excretion of urine by the kidney (antidiuretic hormone). Deficiency of the hormone results in *Diabetes Insipidus* not to be confused with *Diabetes Mellitus* or sugar diabetes. In diabetes insipidus the patient produces enormous quantities of dilute urine. He consequently has a prodigious thirst and consumes astonishing quantities of fluids. Treatment is by replacing the missing hormone.

Thyroid The thyroid gland in the neck secretes an iodine-containing hormone called thyroxine. Excess of it causes *hyperthyroidism*, *thyrotoxicosis* or *Grave's disease*. Lack of it produces *cretinism* in the growing child or *myxoedema* in the adult. Thyroxine is concerned with the metabolic rate of cells throughout the body or the rate at which they work as well as with the proper growth of developing tissues especially the brain. Too much thyroxine as in thyrotoxicosis leads to overactivity, warm sweats in an over-excitable patient whose pulse is rapid and who is eating ravenously to try to replace the wasted energy. In spite of his appetite he is very thin, and he often has bulging eyes for a reason not understood. Treatment is by drugs which neutralise the thyroxine or by cutting out some of the gland. A *cretin* is a child usually born with insufficient thyroid. He is destined to grow poorly and to mental subnormality of a permanent and distressing kind. If the condition is diagnosed soon after birth treatment with thyroxine can avert most of the trouble. In myxoedema thyroxine is deficient in an adult. They become slow in all their bodily processes, the hair thins and their flesh is puffy with a dry wrinkled skin. Treatment is by thyroid replacement. *Goitre* simply means enlargement of the gland. It may be accompanied by overactivity or underactivity or with little functional change. One variety (Derbyshire neck) occurs in areas short of iodine in the soil and drinking water.

Adrenal Cortex The adrenal or suprarenal glands sit as the name implies, one on top of each kidney. There are two distinct parts: the cortex or outside which secretes steroid hormones, and the *adrenal medulla* or core which secretes adrenalin. There are many different steroid hormones in the adrenal cortical secretion, which look after such diverse matters as sodium and potassium balance, sexual function, the reaction of the body to stress and the regulation of sugar levels. *Addison's disease* (not to be confused with Addisonian anaemia) results from adrenal cortical insufficiency and is often due to destruction of the gland by tuberculosis. There is weariness

mauve pigmentation of skin creases and mucous membranes. They are short of sodium and have excess potassium. Treatment is with cortisone (replacement of the missing hormone) and by extra salt by mouth for the lack of sodium. *Cushing's disease* is due to excessive adrenal cortical function and sometimes also occurs in patients treated with cortisone for other purposes. They have a striking redistribution of fat in the face, neck and trunk with a ratchet mark similar to those acquired by most women during pregnancy. The facial obesity makes them moon faced and female patients may suffer masculinisation with deepening of the voice and hirsutism.

Testes The male testes as well as producing sperm are also endocrine glands producing steroid hormones known as androgens. They are mainly concerned with maintaining secondary sex characteristics. At the time of puberty the controlling secretions from the anterior pituitary begin to appear and androgens are produced. There is a whole range of rare disorders resulting in everything from precocious puberty to delayed puberty. It should be born in mind that the normal time of puberty can vary by several years from one boy to another.

Ovary The human ovary has two functions to produce ova or eggs and to produce two hormones—oestrogen and progesterone. These functions begin at puberty one of whose features in the female is the onset of menstruation or menarche. Just as in boys the timing of normal puberty is very variable but on the average girls achieve puberty before boys. As social conditions improve the age of menarche is getting younger generation by generation. All the secondary sex characteristics are under the control of the ovarian hormones which are released in response to the appropriate anterior pituitary hormones. The changes which occur in the womb and elsewhere in the intervals between menstrual periods and the periods themselves are controlled by a cyclical or rhythmic secretion first of oestrogen and then of progesterone by the ovary. This cycle is upset by pregnancy to allow the development of the embryo. It can also be upset by taking certain combinations of the two hormones by mouth. These can prevent the formation of ova and are a popular form of contraception. In late middle age the ovaries lose their function the menstrual cycles cease to occur and reproductive life is at an end. This is called the *menopause* or change of life and is sometimes accompanied for a time by distressing symptoms due to a temporary imbalance between oestrogen and progesterone. Many sexual functions however continue well after the menopause into old age and these can include a continuing libido or sexual desire.

Parathyroid Four tiny parathyroid glands are buried behind the thyroid gland and are responsible for regulating the body calcium and phosphate. They are therefore particularly important for the building and maintenance of bones and teeth. Since a proper calcium level in the blood is necessary for muscle (including heart muscle) contraction and for correct functioning of nerves disorders of the parathyroids can give rise to muscular spasms as well as loss of bone calcium. The latter can result in fragility and fractures. Overactivity of the glands leads to too much calcium and the formation of stones especially in the kidney.

Pituitary We end this section with a mystery gland. Like the pituitary it is small—about the size of a pea—and sits well back at the base of the brain. It was endowed in ancient times with metaphysical properties all of which remain speculative. In fish and lizards and certain lower vertebrates it is a kind of third eye and receives light. In higher mammals like ourselves it is so far from any source of light that it could scarcely do so. It can be removed without harm. Indeed it normally becomes calcified and

inactive about the time of puberty and its position seen on X rays of the skull can be a good guide to whether the brain is being pushed to one side by an abnormal mass.

DISEASES OF THE URINARY SYSTEM

Everyone knows what kidneys look like—in fact the term kidney shaped is used to describe other objects. Within the kidneys the blood vessels carrying waste materials subdivide and finally end up in little coils or glomeruli through which waste products are filtered into the other system the system of tubes which beginning as tiny cups around the glomeruli become larger and larger until they join the ureter passing out at the root of the kidney the hilum a point at which both the veins and tubes enter and leave. The kidneys of course lie one on each side in the loins so that if one puts one's hands on the hips and then slides them farther back they will cover the area over the left and right kidney. The ureters pass down on each side to the bladder which is the storage tank of the products excreted by the kidneys and lies in the mid line down low in the abdomen. It is somewhat pear shaped and at its base in men there lies the prostate gland—a gland which apparently has few functions but can be a nuisance. Its only known function is that it adds something to the semen from the testes without which the semen would be sterile. Then from the base of the bladder a single tube the urethra passes to the outside. One can in fact visualise the urinary system as a capital Y in which the two upper limbs are the ureters the place where they meet is the bladder and the single limb at the foot is the urethra. Clearly then there may be diseases of the kidneys of the ureters of the bladder of the prostate gland or of the urethra.

The amount of urine may be increased or diminished. It is increased in the following conditions after drinking excess of fluids after taking drugs (known as *diuretics*) which are given to increase the flow in diabetes of both types—mellitus and insipidus in some types of chronic kidney disease and finally in emotional states of excitement. It is decreased in the following conditions acute nephritis any disease in which fluid is being lost in other ways such as diarrhoea or sweating in fevers when the fluid intake is small and when both ureters are blocked by stones. Passing a great deal of urine is known as *polyuria* passing very little as *oliguria* passing frequent small amounts is simply called *frequency*. Normally the urine is acid but in infections of the bladder it may become alkaline owing to decomposition by bacteria. Abnormal substances or normal substances in abnormal quantities may occur in the urine and give the doctor an indication of what is wrong. In fact urine analysis is a very important part of medical diagnosis. Thus urea is a normal content of urine which is increased in fevers wasting diseases or diabetes the amount of urea is to some extent a measure of the degree of tissue breakdown. Uric acid is found in small quantities in normal urine but the amount is increased in fevers and after an attack of gout (uric acid is important in the causation of gout but has nothing at all to do with rheumatism in general so one may disregard the advertisements in the popular Press showing unpleasant pictures of joints with sharp crystals of uric acid which are alleged to cause the pain of rheumatic disease). Oxalates are not ordinarily found in urine but since they occur in such foods as rhubarb and strawberries and some people are unable to deal with them such individuals may develop stones or have pain on passing urine after eating oxalate containing fruits.

Two very important substances which ought not to be in normal urine are albumen and sugar. Albumen is a protein and its presence in the urine indicates that the filters of the kidney are leaking—they are allowing protein to pass out which ought to remain in the body. Albumen is easily tested for and its presence may indicate kidney disease or nephritis as it is usually called by doctors. On the other hand small amounts of

albumen occur in fevers and in nervous conditions—*functional albuminuria*. Sugar too should not be present but its presence does not necessarily indicate diabetes for small amounts may occur in nervous conditions or in some people after taking large quantities of carbohydrate.

Blood in the urine may give it an appearance which varies from bright red to a dark smoky colour. It is found in many diseases: acute nephritis, stone tumours poisoning by certain drugs, infections such as bilharzia or malaria, papilloma (i.e. non-malignant tumour of the bladder) after injury in high blood pressure, scurvy and blood diseases. Sometimes it occurs for no known reason at all.

It will be remembered (or if it is not you can look it up on p. 28 (1)) that streptococcal infection of the throat may cause in some people disease of the valves in the heart or endocarditis. In such cases although the germ is found in the throat it is not found in the heart or indeed anywhere else in the body. *Acute nephritis* occurs in the same circumstances with the sole difference that the kidneys instead of the heart are affected. The disease appears to be an allergic reaction to the toxins of the streptococcus. The patient often a child has a sore throat (and even this may be absent or fail to be noticed) or sometimes the infection may arise from other sites: after scarlet fever, erysipelas, burns and disease of the ear. A few days later there is headache, vomiting, pain in the loins, slight rise in temperature and especially typical is *drowsiness* or oedema. This begins in the face first around the eyelids and then affects the ankles; later it may become more general and affect the rest of the body. Blood and albumen are found in the urine and the blood pressure is slightly raised. The outlook is usually good if the kidneys are rested by reducing the amount of protein taken in and also the amounts of salt and water. When this is done the inflammation soon goes and no permanent harm results. In other cases however if treatment is inadequate or the condition severe the symptoms may go but the albumen found in the urine persists. This means that permanent damage has been done and although there may be nothing else to show for many years *chronic nephritis* develops. In this case the blood pressure continues to rise and since the filters of the kidneys no longer work efficiently urea, the principal waste product of the body to be excreted in the urine, is retained in the blood and only small amounts escape from the system. Hence chronic nephritis sooner or later leads to heart failure or hemorrhage in the brain from the rising blood pressure or to the form of poisoning known as *uraemia* which results from the retention of urea in the blood. *Uraemia* may come on suddenly or gradually but ends in progressive coma, drowsiness and unconsciousness. There may be convulsions similar to those of epilepsy, high fever and difficulty in breathing to complicate the picture.

Another type of nephritis which seems to have nothing at all to do with streptococcal infections and the cause of which is completely unknown is *nephrosis*. Developing in early adult life, its onset is insidious and the patient first shows signs of oedema in his white and puffy face and the swelling of his legs. (It should be said here that if you have swelling of the ankles or elsewhere you would be foolish to jump to conclusions for such swelling is common in many diseases—in heart disease in allergic conditions in neurotic illness and even just from hot weather.) When the urine is examined in a case of nephrosis it is found to be full of albumen and as in chronic nephritis the blood urea starts to rise. The end results of nephrosis are the same as those of chronic nephritis and depend upon the damage originally done.

The modern druggists of the chlorothiazide group help to control the oedema and provided enough healthy tissue remains remove both the fluid and the waste products. In advanced or more serious cases artificial kidneys can be used but as yet the transplantation of a kidney is largely in the experimental stage.

Pyelitis is an infection of the pelvis of the kidney, that is to say of the part where the ureter leaves the kidney. It is usually caused by the bacillus coli which is normally present in the

body or by the streptococcus. These germs may reach the ureter through the blood stream or may pass upwards from the bladder. Obstruction anywhere in the urinary tract which causes the urine to stagnate is liable to cause pyelitis. Symptoms come on suddenly with high fever, pain in the loins (the infection is usually on one side only and is commoner in women) and pain in the abdomen. When urine is passed there is a burning sensation and it is passed frequently and in small amounts. On examination the urine is found to be highly acid and full of bacilli, coli or whatever the causative germ may be. Pyelitis is fairly readily treated by the antibiotics or sulphur drugs. Plenty of fluids should be given and the urine made alkaline by administration of alkalis.

Cystitis means inflammation of the bladder, either acute or chronic and its causes are much the same as in the case of pyelitis. There is pain over the lower abdomen, frequency and sometimes slight fever. The treatment is as for pyelitis. *Urethritis* is an inflammation of the urethra with burning pain on passing water and frequency. The most serious cause (although it can usually be easily dealt with now) is gonorrhoea. But non-specific urethritis is common and in this case various germs or none may bring about pain and frequency; there is often a large neurotic element. Urethritis should be regarded as probably due to gonorrhoea which has already been discussed elsewhere when there is a thick creamy discharge from the penis or discharge in women following sexual intercourse with an infected person.

Kidney stones or *Renal calculi* sometimes form and as in the case of gall stones what causes them is not certain. They may be caused by disorders of metabolism—that is in the inability of the body to deal with calcium, proteins, uric acid and other products, or by vitamin deficiency, obstruction in the urinary tract and urinary infections. But when a stone or stones are formed various events may occur: thus it may remain in the kidney and cause no symptoms or it may cause repeated attacks of pain, infection and blood in the urine (hematuria) or it may completely block the passage of urine from the kidney to such a degree that it degenerates and becomes useless or lastly it may pass into the ureter and when this occurs very severe pain known as *renal colic* will occur. A stone passing down the ureter into the bladder may become stuck in the urethra although this is uncommon since a stone small enough to get down the ureters is likely to be capable of manoeuvring through the rest of the tract. In fact about 80–90 per cent of stones are passed spontaneously. Stones not passed spontaneously may have to be removed by operation but whether this is undertaken or not depends on various factors such as the general health of the patient, the amount of trouble caused by the stone and the health of the other kidney—for it is dangerous to operate on one kidney unless one is sure that the other is functioning efficiently.

If a stone blocks the passage of urine on one side for any length of time *hydronephrosis* may result in which the part where the ureter enters the kidney swells with the retained urine. Ultimately much of the kidney may be destroyed by the back pressure. The same effect may be produced by kinking of the ureter or anything else which causes obstruction. Sometimes children are born with hydronephrosis and when the dilation is due to kinking of the tube the condition may be intermittent with attacks of renal colic during which only small amounts of urine are passed. This is followed with relief and the passage of large quantities.

Tumours and Cysts. The kidney may also be the site of tumours and cysts which produce pain in the loins, sometimes a lump over the kidney which can be felt and blood in the urine. Cancer of the bladder is a serious condition in which the bladder may have to be removed, so the urinary flow has then to be directed elsewhere. Either the ureters are brought out on to the skin surface, a procedure known as *cutaneous ureterostomy* or they are implanted in the large bowel so that the urine flows out with the faeces. This is described as *uretero-colostomy*.

There may also be benign tumours of the bladder or *papillomas* which are soft and bleed easily. A great deal of blood is passed but there is usually little or no pain. In this and similar diseases of the bladder examination of the inside of the organ is carried out by means of a cystoscope, a thin tube which is passed up the urethra and has a small electric light at the end which enables the surgeon to see what is going on. Instruments may also be passed through the tube and simple papillomas can be cauterised. Similar instruments are used in the examination of the stomach (gastro-scope) and the bronchial tubes (broncho-scope). When some obstruction in the outlet of the bladder or in the urethra occurs the bladder of course fills with urine which cannot be passed and very painful distention occurs. In this case an attempt may be made to pass a catheter, a thin rubber tube, into the bladder to relieve the tension or if this fails a *suprapubic cystostomy* is performed—an incision is made in the abdomen over the bladder and a tube inserted into it through which the urine escapes. This is ordinarily a temporary expedient and later when the patient's health has improved an attempt will be made to remove the cause of obstruction. The most common cause of such obstruction is enlargement of the prostate gland at the base of the bladder which surrounds this area and the beginning of the ureter. About 40 per cent of men over sixty have some degree of obstruction due to this cause and about 20 per cent of these require operation. The gland is about the size of a walnut and as we have seen its function is to supply part of the fluid which makes up the semen, the male sex secretion. Enlargement of the prostate may be benign or malignant and although nobody knows just why such benign enlargement tends to occur in most men in later life. There may be no symptoms but characteristically there is frequency during the day and the need to get up at night to pass water. The flow of urine being impeded by constriction of the urethra, the passage is less forceful than normal and there is a tendency for dribbling to occur. If the obstruction is severe and not relieved the back pressure may be transmitted to the ureters and kidneys resulting finally in kidney failure and uræmia. The prostate except in cases of very mild enlargement has to be removed either through the abdomen or through the perineum (the part of the body lying between the sex organs and the anus). Sometimes in less serious cases it is possible without an incision to cut away the obstructing part by an electrocautery inserted as is a cystoscope through the urethra. Prostatectomy was once a serious operation, all the more so because the patient was usually elderly and not in good condition but new techniques and the use of antibiotics have greatly improved the outlook.

Cancer of the Prostate is always serious but if discovered in time it can be operated on successfully. The gland of course has to be completely removed in inoperable cases or in patients unfit to stand operation the tumour may be treated by means of female sex hormones which cause it to shrink and may prolong life by some years.

DISEASES OF THE NERVOUS SYSTEM

The nervous system consists of the Central Nervous System and the Peripheral Nervous System. The brain and spinal cord make up the former. The latter consists of the nerve fibres by which the Central Nervous System is connected to all parts of the body. Human beings have a more complicated brain than any other animal species but it is only its complexity which makes it different from the brains of other mammals like rats and pigs and cows. We do not have the largest brains since whales for example have much larger ones. Ours is not even the largest for the size of the body. Mice and dolphins and several other creatures have relatively larger brains when compared with body weight. Furthermore the cells and materials of which our brain is composed are virtually identical with those in other mammals and its living properties are also the same.

Before describing some of the diseases of the nervous system it will be helpful to say a little

about how it is made and how it works. Each human brain probably contains about ten thousand million (10 000 000 000) nerve cells and perhaps four or five times this number of supporting glial cells. Each nerve cell has many long thin branching projections called dendrites rather like the branches of a tree leading to many thousands of twigs for each single nerve cell. At the end of each twig there is a special structure called a *synapse* by which contact is made with other nerve cells. It is through these connections that very large numbers of nerve cells give information (or send impulses) to each other so that they can be co-ordinated. As well as these dendritic branches each nerve cell gives off one large trunk called the *axon* down which final messages are sent as the result of all the information it receives from its dendrites. Some axons are many feet long. Some end in another synapse by which the outgoing message is passed to yet another nerve cell. Some axons those of the peripheral nerves end directly on organs like muscles or glands instructing them and making them work.

Messages are passed along dendrites and axons as electrical impulses. These are generated in the nerve cell body. They are modified according to information received from other nerve cells and propagated down the axon. It is this superficial resemblance to a series of electrical cables which has given rise to comparisons of the brain with a telephone system or a computer and as long as it is realised how infinitely more complicated each brain is than any known computer the comparison is not a bad one. However the brain generates its own electric power from the food brought in its own blood supply and no spare parts or spare cables are available if the originals should get damaged except in peripheral nerves. Furthermore the contact of one nerve cell with another through a synapse is not an electrical contact and neither is the contact between a nerve and the muscle or other organ it is controlling. In both cases the connection is chemical. Thus when an electrical impulse arrives at the end of the nerve fibre a chemical is released into the gap between it and the next nerve or organ and it is this chemical which carries the stimulus forward. There is also an arrangement to neutralise the chemical transmitter when the impulse has been transmitted. So the resemblance to a telephone exchange or computer can sometimes be misleading.

Many of the nerve axons which transmit electrical impulses are clothed in fatty *myelin sheaths* a little like the plastic insulation around an electric wire. Here again the resemblance is only partial since the myelin sheaths are interrupted at regular intervals and these gaps in the insulation play an important role in transmitting the impulse. One of the important functions of the non-nervous glial cells of the brain is to manufacture and maintain the myelin sheaths.

Most of the functions of the brain are quite unknown and even the ones we know about are very poorly understood. It is assumed to be the organ of higher mental function of the mind and intellect but there is surprisingly little evidence for this, and no one has any idea what physical structures or mechanisms subserve these functions. The brain is known to control all bodily functions by means of motor and other nerves which carry impulses from the brain outwards to all parts of the body. Sometimes these are under our voluntary control mostly they are involuntary reflex or automatic. Reflex actions are the result of impulses passed inwards from the body towards the brain by means of sensory nerves. Information arriving in the brain about the various sensations like heat, pain, touch, position, the need for saliva or gastric juice or even the thought or smell of food, are acted on in the various centres in the brain. These send out instructions down the motor or secretory nerves which instruct the muscles or glands to take appropriate action. Thus a reflex has a sensory ending which appreciates some sort of sensation. This is converted into an electrical impulse which is sent towards the brain or spinal cord along a sensory or afferent nerve. The impulse arrives at a centre in the central nervous system which co-ordinates all the relevant information and issues instructions. These travel

as impulses outwards along efferent nerves towards effector organs like muscles or glands and an appropriate action occurs automatically. The pathway from sensory ending to effector organ is called a reflex arc. Many reflex activities are partly under voluntary control although mainly automatic. If you touch something hot you will automatically withdraw your hand. But if it is a hot china cup which has cost you a lot of money you are capable of overriding the tendency to drop it at least for a time. Breathing is automatic but it can also be controlled again at least for a time.

Clearly the brain is a very delicately organised piece of machinery and its cells are extremely specialised for their job. Achieving this kind of specialised perfection brings in its difficulties however and the brain cells have become highly dependent on the proper functioning of the other body systems especially the blood circulation, the respiratory system and the systems regulating the detailed nutrient composition of the blood. Failure of these systems even for a very short time can damage the nerve cells. Nearly all death from whatever original cause is produced thus way by an ultimate interference with nerve cell function.

We have already mentioned that the brain and spinal cord are unable to repair or replace any components which get damaged. The vulnerability of the brain is even more obvious when it is realised how easily damage and destruction can occur. For example unless a rich supply of oxygen and glucose is continuously arriving in the blood stream brain cells will cease to function in a few seconds and will die in a few minutes and they can never be replaced. This is in marked contrast to other tissues of the body. The leg for example may carry on for over half an hour without any blood at all because the muscle and other cells can find other ways of surviving. Thus the brain can be permanently damaged if the blood contains insufficient oxygen (through asphyxia), insufficient glucose or if the blood supply is blocked or if the blood pressure falls. All these are likely to happen to any of us at any time and so there are elaborate mechanisms trying to prevent them occurring. Most of the subject of physiology is concerned with the mechanisms designed to protect the brain and most of us ultimately die because they eventually fail. One of the clever features of the body design is that all the mechanisms which protect the brain from a supply failure are controlled by the brain itself. Thus the brain has itself been made to control the heart beat and the breathing and the many other systems which are needed for its own survival.

In all that follows concerning disease of the nervous system it will be seen that the effects of neurological disease on the patient are the direct result of something going wrong with one of the structures or mechanisms we have described.

Diagnostic Techniques in Neurology The doctor has many ways of testing the nervous system most of which test its various functions as outlined in the introduction. Thus tests of sensation, muscular movement and reflexes of all kinds as well as the special functions of taste, smell, vision, hearing, speech and intellect play a part. X rays only show the skull because it is calcified, the brain not being seen directly. There is however a tiny pea size central structure called the pineal gland which usually becomes calcified with age and this shows up. If for any reason the brain is pushed over to one side of the skull this can be detected by displacement of the pineal. A great deal can be learned about the brain by *arteriography*. In this test a radio-opaque substance is put into the arteries supplying the brain and an X ray picture taken immediately afterwards shows up all the blood vessels. *Ventriculography* is an X ray examination after gas has been introduced into the brain cavities or ventricles which are normally filled with *cerebro-spinal fluid*. *Myelography* is an X ray of the spinal cord after a radio opaque substance has been injected into the space between the spinal cord and the bony vertebral canal which houses it. All these X ray procedures are ways of looking for a change in the shape of the brain or its vessels.

Sometimes radioactive isotopes are put into the blood stream and carried into the brain where they can be detected from outside the skull by counters. *Electroencephalography* measures the electrical waves generated by the brain by placing electrodes on the scalp. *Electromyography* does the same for muscles.

Consciousness and Unconsciousness (Contd.) Everyone knows what consciousness is until he tries to define it. Full consciousness is generally taken to imply not only wakefulness but the total complement of human mental faculties. In clinical medicine however something less than this is usually meant. For example a 'comatose' person or one whose memory is lost (*amnesia*) or one whose powers of speech are lost (*aphasia*) may still be conscious. There is really a continuous gradation between full consciousness and coma passing through drowsiness and even stupor in which condition a patient can be aroused from coma but sinks back into it when left alone. Many different things can cause coma ranging from swelling of the brain compressing it in its rigid box or bone to disorders in other body systems resulting in a failure to provide for the brain's needs. Examples of the first are bleeding within the brain or *brain tumours* both of which occupy space and can only do so by producing compression. In the second category are asphyxia preventing oxygen from reaching the brain, lack of glucose in the blood circulating, failure in which there is insufficient blood or insufficient blood pressure. Fainting is a comparatively minor example.

Sleep and Insomnia Nobody knows what causes sleep why it is necessary and how it helps. It is quite different from coma or even stupor since as much oxygen and glucose is necessary asleep as awake. Insomnia is experienced by everyone at some time and for some reason is very distressing if it persists. There are three forms: failing to get to sleep, intermittent wakefulness and awaking early. Nearly all men sleep more than they think. They should eat light evening meals and avoid stimulants like tea and coffee after midday. Elderly people should realise they need less sleep. Being cold or having a full bladder can be a cause. Or simply not being tired. Sedative drugs are a last resort but they can be useful in breaking the habit of wakefulness. Obviously there may be psychological factors such as anxiety and excitement. *Narcolepsy* or a true inability to keep awake is comparatively rare. Both *narcolepsy* and *insomnia* are really extreme examples of what all normal people suffer from occasionally.

Headache is man's most common pain. Here again we must distinguish between the very common varieties of comparatively trivial significance and the rare ones due to serious causes. Some headaches are due to continuous tightness in muscles of the scalp and are often nervous or psychological in origin. Others result from nose blockage and congestion, sinus problems, eye strain, toothache etc. *Migraine* is a special kind and will be described below. Very occasionally indeed headache is due to serious disease like brain tumour. Most headache results from living it up or being run down, or both. The headache of alcoholic hangover is probably due to dehydration. It can often be avoided by consuming a great quantity of water (a pint or two) before going to bed but few people are prepared to do this in the circumstances. Be careful when using aspirin, which is a useful remedy for headache since it is very dangerous for people with stomach complaints like gastritis or gastric or duodenal ulcer. Occasionally aspirin makes the stomach bleed and this can be so severe as to kill. A safer pain killer is paracetamol. Be particularly careful in treating hangover headaches by patent fizzy remedies. They are very effective but often contain large quantities of aspirin described in small print by its proper name as acetyl salicylic acid.

Migraine This is a very special variety of sick headache and requires special treatment under medical supervision. It has many different forms but usually there is a definite sequence of

events. An attack often starts with some alteration of vision. The patient has shimmering blind spots or other visual disorders. This is followed by a well localised severe headache which may end in nausea or vomiting. The whole thing is caused by a poorly understood disorder of the blood vessels. There are special drugs mostly derivatives of ergot which are effective especially if used when the first signs of an attack appear. Although there is a direct physical cause for an attack it is also certain that some of the trouble is psychological tenseness. People with migraine are often rather anxious, striving and perfectionist people. Also it has been noticed that attacks are much less frequent when the necessary pills are being carried available for use. However as with all other conditions which are partly psychological in origin they are none the less distressing for the patient. It simply means that the treatment is also partly psychological in encouraging him to come to terms with his problems.

Ménière Disease is one of the conditions in which the organ of balance in the middle ear is affected giving rise to *vertigo*, a form of giddiness. It usually begins in middle life in the same sort of person who sometimes has migraine. There is buzzing in the ears and some intermittent loss of hearing as well as vertigo. During an attack the patient may be unable to walk because of his loss of balance and nausea and vomiting are common. Treatment is by special drugs and occasionally an operation on the ear is necessary.

Epilepsy is a symptom not a disease which is common at all ages but especially children. It has been attributed to St. Paul, Julius Caesar, Napoleon and (with more justice perhaps) to Dostoyevsky. Many varieties of attack occur often in the same patient, the commonest and best known being the *grand mal* or major seizure. In this the patient falls down unconscious and rigid and the jaw is clenched so that there is danger of the tongue being bitten. This so called tonic phase is followed within a minute or so by a clonic phase in which the limbs contract rhythmically. The attack ends with the patient going limp and gradually recovering consciousness, a process which may take up to an hour. Occasionally the patient has a brief warning, most often an indescribable feeling in the stomach. There are two common forms of minor seizure one occurring mainly in children and the other more often in adults. The common minor attacks in children are often called *petit mal* or *absence* which well describes the instantaneous and brief loss of consciousness often unaccompanied by any change in posture. Recovery is usually instantaneous. On the other hand in the other forms of epilepsy which arise from various parts of the brain but especially from the lobe under the temporal region there is often a warning similar to that which may precede a major seizure. In these cases the patient shows only confusion no definite loss of posture but automatic activity such as fumbling with buttons, muttering and grinning. Following these attacks there may be a quite prolonged period of confusion in which the patient may wander away and occasionally may be violent. Criminal acts are very rarely carried out in this state.

A large number of people have had one or two fits in their lives particularly at times of physical or psychological stress. Fever or febrile convulsions (often called teething fits in the past) are extremely common in young children and are often thought of as something different from epilepsy since the attacks rarely continue in later years. This form of epilepsy and some cases of *petit mal* are the only forms in which hereditary factors are important in the causation and these are the least serious forms of epilepsy. They are very rarely associated with serious physical or psychological disturbances. Most other forms of epilepsy are due to a scar or other area of brain damage. It is a proportion of these cases which develop the psychological disturbances that are occasionally very serious.

Not every patient who has had one or two fits need necessarily take regular anticonvulsant drugs that is drugs which damp down the abnormal excessive activity of the brain that leads to the attacks. Many drugs are available of which

the most important are phenobarbitone, phenytoin, succinimides and truxidones, the last two being effective only against minor seizures. Which one to use and whether to use one at all is of course quite a complicated judgment and must be left to the doctor. Epileptics often find it difficult to get work because of the reluctance of employers to take on someone who may be more prone to accidents and whose fits may distress other workers. Obviously there are some jobs which epileptics should not do because of the danger involved (from for example moving machinery) and they should not drive a car. A few cases are so severe that work is almost impossible but employers have a duty whenever possible to employ these people whose mental health may suffer greatly if they are made to feel outcasts and who ordinarily are as efficient or even more so as the next man. It is also hoped that employees will become less prejudiced about epilepsy as the general public become less ignorant about medical matters. In this way epileptics will come to be accepted in all those kinds of employment for which they are well suited. If some of the famous men who have suffered from this disease had had to rely on the charity of some employers today the world would have been much the poorer although possibly we could have managed without the generals.

Congenital Malformations. The proper shape of the brain and spinal cord is achieved quite early in development by about the thirteenth week after conception. During this time very slight changes in the fetal environment can produce disastrous malformations. The drug thalidomide for example operated on other body systems while they were passing through this phase of construction. Some viruses can do the same thing. Most malformations are without known cause but it is certain that something went wrong at this very early stage and it only needs a very minor interference with the normal process to do the permanent damage. At about this time the bones of the spine are beginning to enclose or form a roof over the developing spinal cord. Sometimes they fail to complete the process resulting in *spina bifida*. If the coverings of the cord protrude through the defect this is a *meningocele* and if the cord itself protrudes it is a *meningomyelocele*. The whole protrusion may be covered with skin but if it is not the cord soon becomes infected. The effect on the patient is variable according to the amount of damage to the nerve fibres in the cord and there are varying degrees of paralysis and loss of sensation below the area involved together with loss of bowel and bladder control. Much help is often obtained from surgical repair but many cases remain in a distressing condition always and the only really useful attack on the problem is research to find the cause and prevent it happening. The same is true of the *malformations of the brain*. In one of these hydrocephaly the narrow channel is blocked which transmits the cerebrospinal fluid from the chambers within the brain where it is secreted to the outer coverings to be taken back into the blood stream. Blockage of the channel (or aqueduct) results in distension of the brain by fluid enlargement of the head and mental retardation. Sometimes a by pass valve can be inserted to restore normal fluid circulation with very gratifying results. This aqueduct can also be blocked by later disease (meningitis) or injury with the same result. Sometimes the brain fails to form altogether (*anencephaly*) and the child fortunately does not survive after birth.

Cerebral Palsy is a term covering many varieties of *spastic child*. It is thought to be due to brain damage at birth or in early infancy and is depressingly common. Although a great deal can be done for the spastic (they are often of normal intelligence) the only satisfactory approach is prevention and this means expensive research into its causes. Donations, encouragement and offers of practical help please to the Spastics Society 12 Park Crescent London W 1.

Motor Neuron Disease. This is a group of distressing diseases usually occurring in people over 40 in whom the parts of the brain and spinal cord degenerate which look after muscular movement. The group includes *Amiotrophic Lateral*

Sclerosis Progressiva Muscular Atrophy Progressiva Bulbar Palsy and Primary Lateral Sclerosis The results are paralysis or weakness with wasting of the muscles of the body including those concerned with arms legs breathing speaking etc. Nothing whatever is known of the cause and the only treatment is that designed to alleviate the results of the disease. It is uncommon but this is little comfort to the sufferer.

Parkinson's Disease paralysis agitans or the shaking palsy is a common condition which begins in later life over the age of 50. It has three classical features: shaking (or tremor), muscular rigidity and loss of those automatic reflexes which look after bodily posture. This results in a stooping shuffling gait. Later there is a mask-like loss of facial expression with diminished eye blinking. It is a progressive disease but it progresses so slowly that 10 or 20 years may elapse between its onset and incapacity. A good deal can now be done to help these patients with drugs; the most recent of which at the time of writing is DOPA. Occasionally patients have benefited from surgical destruction of small areas of diseased brain. It is important to remember that many elderly people have some tremor of the head or hands called *Senile Tremor* and this is not Parkinson's Disease. It is merely one of the features of achieving advanced seniority as a citizen. See also P82.

Chorea This is a group of diseases in which there is involuntary muscle movement, weakness and emotional instability. There will be clumsiness, awkward gait, twitching of limbs, face, hands, trunk or tongue. They include *Acute Chorea* or *St. Vitus Dance* occurring in children from 5 to 15, *Hereditary or Huntington's Chorea* occurring in a well defined genetic pattern and beginning later, between 30 and 50. *Tics* or habit spasms are not part of these diseases but are often of psychological origin. They are usually eye blinking, head shaking, shoulder shrugging or any other sudden gesture of limbs or face.

Stroke Illness or Cerebrovascular Diseases Strokes are due to diseases of the brain's blood vessels which either burst or get blocked. The same blood vessel disorders cause heart attacks by blocking the coronary arteries supplying the heart. Strokes and heart attacks together kill more people than any other single cause including cancer. They account for one death in every five. Perhaps less is known of the cause of this disease than is known about cancer and much more research is needed to find out if it is to be prevented. The cause of the commonest cancer (of the lung) is now known and it can be prevented by stopping smoking. Perhaps the prevention of strokes and heart attacks will mean an equally difficult abstinence from all those foods which make us fat. At least it is known that being overweight leads to death from these causes just as smoking leads to death from lung cancer.

If any artery supplying blood to any part of the brain is blocked, the territory supplied will die and the bodily functions for which that part of the brain is responsible will cease. The process is called *infarction* of the brain, the dead area being an *infarct*. The blockage is usually due to thrombosis (see P81) of the blood within a vessel, a *thrombus* being a rather complicated clot with a structure of its own. The underlying cause is the arterial disease *atheroma* (see P30) together with stagnation of the circulation. About one blockage in ten is due to a small piece of a much larger thrombus in the heart chambers being flung into the blood stream and impacting in the distant vessel in the brain. This is *cerebral embolism* (see P30). If the area of dead or infarcted brain is not too large the patient will recover from his unconsciousness but will be left with permanent loss of function (paralysis etc.) related to that part of the brain.

When a blood vessel supplying the brain bursts, this causes *cerebral haemorrhage* or *apoplexy*. The vessel may be on the surface (*subarachnoid haemorrhage*) or in the depths of the tissue (*intra cerebral haemorrhage*). Strokes tend to occur in older people, because the associated arterial disease is a product of age and high blood pressure. Occasionally a subarachnoid haemorrhage occurs

in a younger person with an unsuspected malformation of the arteries of the base of the brain known as a *berry aneurysm*. This is a small berry sized blown out balloon due to a defect in the wall of the vessel. Berry aneurysms can often be treated surgically. Intracerebral haemorrhage carries a very poor outlook however since much brain tissue is often destroyed by the escaping blood, especially the deep tissues responsible for the vital functions. Haemorrhage within the brain cavity can also be caused by injury (see *concussion and compression* P19).

Inflammatory Diseases of the Nervous System The membranes covering the brain are called the meninges. Inflammation of these meninges is always by blood born infection or infection following injury is called *meningitis*. Cerebrospinal or spotted fever which used to be common and very much feared was only one variety caused by a germ called *meningococcus*. It is now rare. Almost any other germ may cause meningitis and when the germ is susceptible to one of the antibiotics it is usually treatable. It will usually be necessary to identify the germ by taking a sample of cerebrospinal fluid from a convenient space around the spinal cord in the lower back. When the disease is caused by the tubercle bacillus (*tuberculous meningitis*) the problem is more difficult because the patient is often not so obviously ill until the later, less treatable stages. *Cerebral abscess* or abscess of the brain is very serious because it occupies space in the closed box of the skull and compresses the brain as well as being a destructive process. It may arise due to an infected piece of tissue or pus being carried to the brain in the blood stream from a distant site in the lungs or heart. When the brain or cord tissue is itself inflamed it is called *encephalitis* (brain) or *myelitis* (cord) or *encephalo myelitis* (both). These conditions are comparatively uncommon and are often due to infection with viruses rather than bacteria. Some have no known cause, possibly because many viruses are difficult to identify.

Multiple Sclerosis or Disseminated Sclerosis or the creeping paralysis as it used to be called is the most important of the *Demyelinating diseases* in which the myelin sheaths wrapped around the nerve fibres disintegrate. This only occurs in small areas, or plaques. It is as if drops of acid have been placed at random throughout the brain and spinal cord and have dissolved away the insulating sheaths over sixpenny (or new penny) sized areas leaving the wiring (the nerve fibres) running through as before. But this small loss of insulation is enough to spoil the carefully graded electrical impulses and thus the bodily function subserved by those fibres is lost. So there are apparently random losses of sensation, movement, bowel or bladder control, speech etc. according to which collection of nerve sheaths happen to have been attacked. Thus it is that no two cases are alike and many are difficult to diagnose. Many have even been labelled maligners in the early stages so bizarre are the signs and symptoms. The disease is not a killer. It smoulders on year after year often beginning in the late teenager and getting steadily more incapacitating over many decades. No one can predict how quickly it will deteriorate and in some cases many years will go by before yet another episode of more myelin sheath destruction. Neurology has more than its share of completely mysterious diseases. This is perhaps the most mysterious and it is no very uncommon case. The many years of disability in each individual case make it at least as disabling as far commoner diseases which run a much shorter course. There is no more humbling disease for the medical scientist, but the faith must remain that with more and more research this crippling condition too can be prevented. The Multiple Sclerosis Society, 4 Tachbrook St. London S.W.1 looks after patient welfare, supports research and is very deserving of your donations. As in all other crippling conditions there are countless ways in which you can help the victims at no great expense. Visit them. Help with their shopping and other day-to-day needs. Take them out. And even write to your member of parliament demanding a better deal for the disabled who are

still in spite of recent legislation among the most downtrodden and deserving of our neighbours.

Myelin sheaths are largely made of fats so it is small wonder that the brain has its full share of complicated biochemical mechanisms for dealing with fat and manufacturing it. Hand in hand with this is a host of comparatively rare diseases known as the *lipidoses* which are basically disorders of fat biochemistry. Among the best known are *Tay Sachs disease*, *Niemann Pick disease*, *Caucasian disease* and *Hurler's disease* and it is beyond the scope of *Peas* to describe them in detail.

Brain Tumours The brain is no exception to the rule that any cell in any tissue of the body can suddenly begin to disobey the body's rules regarding its growth and multiplication. A totally unknown mechanism governs how many cells of a certain type there ought to be and calls a halt to cell multiplication when this number is reached. Every now and then one of them turns a blind eye and goes on dividing and the result is a tumour or lump of anarchic cells which obey no rules. Tumours are commonest in cells which normally go on dividing throughout life in order to replace those lost by wear and tear. Examples are the cells lining the air passages in the lung or the alimentary tract in the stomach or large bowel. Fortunately for the brain there is little cell division once it has grown. Nerve cells cannot divide at all in adult life and the supporting glial cells only do so in response to injury. Therefore primary brain tumours are much less common than those elsewhere. Also many brain tumours like many of those elsewhere, are benign or innocent tumours. They are not cancerous and need only be removed for the patient to be completely cured. The brain however is at two major disadvantages compared with other tissues when it comes to tumours. One is that all tumours as they grow take up space and space in the skull is already fully occupied. Thus even an innocent tumour can compress the brain within its rigid box of bone and become most dangerous until it is removed. The second disadvantage is due to the very large blood supply of the brain. Cancer in other parts of the body spreads partly by sending small pieces of itself to other tissues by way of the blood stream and those tissues like liver, lung, kidney and brain which have a big blood supply naturally receive more than their share of other tissues tumour. These secondary deposits or *metastases* cause compression and other trouble in the brain much more frequently than the brain's own primary tumours. Indeed convulsions or other signs of brain disorder may be the first indication that there is a primary tumour in the lung or breast or elsewhere.

Head Injuries are dealt with in the section on Physical Injuries (P19) where a great deal of space is given to the effects of most First Aid emergencies on the proper functioning of the brain and spinal cord.

Diseases of Peripheral Nerves Compared with the nerves of the central nervous system (brain and spinal cord) the peripheral nerves are comparatively rarely affected by disease. They have some similarities of structure with central nerve fibres in that their fibres are often covered with myelin sheaths and are arranged in bundles. A special feature however is that they are encased by connective tissue sheaths and it is probably these which allow a peripheral nerve to grow again or regenerate after it has been cut or damaged. Central nerve fibres are unable to do this. After injury of a peripheral nerve the part away from the centre is cut off from its parent cell body and it dies. All function whether motor or sensory is lost. But in the course of many months the central surviving part grows into the connective tissue sheaths which act like tubes to guide the new nerve to its destination. Provided the cut ends are close enough together and correctly aligned and provided enough fibres reach their correct destination good functional recovery is possible.

A disorder of a peripheral nerve is called a *neuropathy* and means nothing more than that. There are many kinds. One of the most distressing

is *trigeminal neuralgia* again fortunately rare. The trigeminal or fifth cranial nerve has a motor and sensory territory on the face. In this condition there are paroxysmal episodes of extremely severe pain which may resist all treatment except destruction of the nerve itself with consequent facial paralysis and loss of sensation. At the other more trivial extreme are the occasions when a leg goes to sleep or gets pins and needles after crossing it and pressing on a nerve for too long. *Bell's Palsy* is sudden loss of function of the seventh cranial nerve and there is again paralysis on one side of the face which usually recovers in time. Some bacterial diseases especially leprosy invade the nerves themselves. Chronic alcoholism may affect the nerves as may diabetes probably by interfering with the nutrition of the nerve cell. So may exposure to arsenic or lead or an unpleasant nerve poison which may contaminate cooking oil known as TOCP or triorthocresylphosphate.

Muscular Dystrophies These are a series of diseases of muscle in which there is progressive wasting and weakness of muscle the causes of which are entirely unknown. They are divided up according to the age of onset and the muscles involved. *Duchenne's muscular dystrophy* occurs in the first decade of life. It affects most of the muscles eventually including the heart muscle and those concerned with breathing and so the outlook is not good. Other forms are inherited.

Myasthenia Gravis This is a strange disorder of the mechanism which transmits instructions from nerve to muscle at the neuromuscular junction. There is extreme weakness of muscles after they have been used resembling in some respects the weakness following the administration of curare or arrowpoison. It is often associated with disorders of the thymus gland. The drug neostigmine reverses the neuromuscular disorder and removal of the thymus is also sometimes effective.

MENTAL DISEASES

Psychosis

Mental diseases are divided into psychoses (i.e. insanity) and neuroses (i.e. what is ordinarily known as nerves). Psychoses in their turn are divided into organic and functional—those due to physical disease and those in which no physical cause has been discovered. In point of fact the distinction into organic and functional is rather meaningless for if we accept the modern view of psychosomatic medicine which regards the body and mind as a single unit it is clear that organic disease brings out psychological defects which were already there and that functional disease must in the final analysis be the result of physico-chemical causes even if this is brought about by mental stress.

Organic disease results from poisoning of the nervous system by such poisons as alcohol, carbon monoxide or lead, vitamin deficiencies as in pellagra, infections such as syphilis and degeneration of the brain either primary or as a result of poor blood supply. In all cases its main symptoms are confusion, signs of other disease and loss of memory. Alcohol leads to various conditions in *delirium tremens* heavy bouts of drinking and in *delirium* (D.T.s) confusion, hallucination—although not necessarily of pink elephants or rats. It is a serious disease but the outlook is much improved since it was discovered that injections of concentrated vitamins B and C in the form of Parentovite can help. In more chronic cases *Korsakow's syndrome* manifests itself in the form of mental deterioration and memory defects. There can be little doubt that previously existing mental instability is a predisposing factor in these conditions. The same may be said of *general paralysis of the insane* or G.P.I. and in this case the immediate cause is syphilitic infection of the nervous system. Nevertheless, of all the patients with chronic syphilis only a small number get syphilis of the nervous system. G.P.I. is typically associated with the usual symptoms of organic disease and delusions

of grandeur—for example a man with this disease may go out and buy several expensive cars in one day. However, it is not uncommon to find G.P.I. associated with severe depression—again the picture depends on the previous personality. The association of the above symptoms with a positive Wasserman test—which proves the presence of the spirochete in the blood—indicates neurosyphilis. When the lower centres of the nervous system are affected the disease is known as *tubes dorsalis* in which there is difficulty in passing urine, limb pains, inability to stand when the eyes are closed and finally difficulty in walking. The patient becomes paralysed and ultimately bedridden. Treatment is with penicillin.

People age at varying rates so that some are hale and hearty at eighty or ninety whereas others are old at sixty or seventy. They present the typical picture of old age—second childishness and mere oblivion—sane eyes, sane teeth, sane everything. When this condition, which is caused by degenerative changes in the brain or by defective blood supply resulting from arterio-sclerosis, is pronounced we speak of *senile psychosis*. There is mental confusion, forgetfulness and delusions in which the previous personality defects which we all have are accentuated. Such patients may have to be put under special care, but the process is largely irreversible.

The functional psychoses are two in number—schizophrenia and manic depressive insanity. In *schizophrenia* which when it occurs in early adult life is known (or used to be known) as *dementia præcox* the symptoms are bizarre. There are delusions and hallucinations so that the patient often believes himself to be persecuted and hears voices which say objectionable things to him. Sometimes the schizophrenic is wildly excited and in other cases he goes into a state of stupor which is described as a catatonic state. Although the disease is described as functional, recent discoveries seem to suggest that there is some derangement of the blood chemistry. Treatment by insulin and the new tranquillising drugs has revolutionised the outlook in this admittedly serious disease. Indeed some cases of psychosis are more easily treated than neurotic patients since the former respond to physical methods whereas the latter may require fairly prolonged psychotherapy (psychological treatment) and are less responsive to drugs.

In cases which do not respond to other methods, the brain operation known as *leucotomy* may be performed. Leucotomy is also performed to alleviate intractable pain as in incurable cancer, but some of the ataraxic drugs (tranquillisers) are probably equally useful for this purpose. Leucotomy involves the severing of the connecting nerve fibres between certain areas of the brain and the results are often favourable, but in fact the operation should be performed only in cases where the outlook is otherwise very poor. Chronic severe neuroses, frequent attacks of manic depressive psychosis, severe chronic depression, and schizophrenia which has not responded to other forms of treatment. The operation reduces anxiety, fear, aggressiveness and agitation, but may result in the less desirable symptoms of apathy, impaired judgment, lack of self-control and loss of initiative.

Schizophrenia developing in later life is likely to be less dramatic in origin, and the delusions tend to be more systematised—that is they take a persistent form which does not change from day to day. This type of the disease is known as *paraphrenia*. In those beyond middle age the rare but dangerous condition described as *paranoia* may develop in which there are no hallucinations and the only symptom is a completely systematised collection of persecutory delusions, which on recital may sound entirely convincing even to the ordinary doctor. Such people are dangerous precisely because they are so plausible and they fill the ranks of the liars, the trouble makers and the political and religious eccentrics. One such patient known to the writer spent his life in a mental hospital from which he had parole employing this to form a society propagating highly eccentric sexual and political beliefs. It says little for the intelligence of the general population that his meetings were invariably crowded out (although, of course, when one reads of the people who apparently believe that the various

fictitious families on radio or television—really exist, one need not be surprised at such examples of communal dotiness even if one may despair of democracy).

Manic-depressive insanity is characterised by mood swings in which the emotions alternate between wild elation without obvious cause and equally causeless depression. However, the picture is not quite as simple as this. In phases of mania or excitement may occur without depression obviously following or there may be a single attack of depression with no manic phases. The disease may be absolutely incapacitating or there may be periods of relative normality typically then manic-depressive insanity is a disease of alternating moods. The depression responds to electroconvulsive therapy or E.C.T. but mania is less responsive to treatment. However it ordinarily remits of itself. Sometimes in middle age *involutional depression* occurs and this in the vast majority of cases is cured by E.C.T. As in the case of schizophrenia drugs are increasingly used for depression.

Neurosis.

The main neuroses are anxiety neurosis, hysteria and obsessional neurosis. *Anxiety neurosis* is an illness in which the main symptom (as the name implies) is anxiety. There is fear which rationally the patient knows to be groundless, there may be anxiety attacks in which the heart pounds, the patient feels he is going mad, is unable to sleep and worries for no reason at all. In hysteria anxiety is largely absent, but there may be apparently physical symptoms ranging from paralysis of the limbs to blindness, deafness, inability to write and lapses of memory (the so-called hysterical fugues or loss of memory). Typical of *hysteria* is the fact that the patient is less worried by his symptoms than would be expected from their apparent seriousness; this is what the early psychiatrists described as *la belle indifférence*. The reason for the indifference is simple—it is that the paralysed individual *wants* to be paralysed, the blind *wants* to be blind, the deaf to be deaf (there are none so blind—or deaf—as those who don't want to see or hear), and the person who doesn't want to write conveniently finds that he cannot.

Generally speaking neurotic people are suffering from a failure to face up to reality. They are not physically ill and are largely the end result of a faulty upbringing. It is wrong to suppose that the only bad families are those in which the children are ill-treated; much the worst ones are those in which children are spoilt, the parents possessive and the wrong kind of love is dispensed. Neuroses are the result of a conflict between primitive desires and what the individual has been brought up to believe he should be. For example, before an examination a student may develop a nervous breakdown because he fears failure when he has been brought up to expect success. The excuse of course is overwork—an entirely non-existent condition. With his breakdown he solves his problem: he avoids the fear of failing and preserves his self-respect, he has been ill. Similarly the soldier with a shell shock (another non-existent condition) has a conflict between his sense of duty and his fear of death, which again is solved by becoming ill. Or to take a final example a woman feels the duty to look after her ageing mother. But she also wants to get married. So she unconsciously develops a neurosis which says in effect, 'I should like to do my duty in looking after my mother, but unfortunately I am unable to.' There is an unconscious rebellion on the part of the mind.

Neuroses, in effect, is not a disease—it is a self-inflicted injury, a form of maladaptation to life. The neurotic, no matter how much he suffers, does not want to get well; he has found some way of getting along, even if a foolish way, and he intends to keep it. Often his symptoms are the sort of excuse that say, 'If only I wasn't ill, what wouldn't I be able to do!' The neurotic is a person who is different and is afraid to be himself; his problem is a conflict between being ordinary—like other people—and being what he was supposed to be.

Obsessional Neurosis is a more severe type of neurotic illness for although in anxiety neurosis we find such symptoms as phobias—irrational fears of open spaces, closed spaces, animals and so on, obsessional states are characterised by compulsive feelings that certain acts must be performed or certain thoughts thought. In a mild form we all have obsessions: we feel that we must walk on the spaces between paving stones that we must touch lamp posts and so on. But when this type of compulsion gets to the stage when we must go back several times to make sure the lights have been put out when we feel the need to wash our hands every few minutes, become obsessed with numbers on cars or dates on coins, then it becomes a nuisance and requires treatment. The obsessional neurotic is a person who feels that life must be controlled; he is a creature who moves in predestinate grooves—he is not even a bus but a tram. His symptoms are an attempt to devise self-imposed rules which will control the unconscious desires of which he is so afraid.

Neurasthenia is an entirely imaginary condition allegedly due to exhaustion of the nervous system. Since no such condition exists, we need not bother with it. Nervous cannot be treated by feeding the nerves (which are perfectly normal). They can be helped by such things as sedatives but not cured. *Neurosis has nothing at all to do with disease of the physical nerves, no nerve tones do not exist and anyone who asserts that they do is a humbug.*

Psychopathic Personality is the term given to anyone who has different standards of behaviour from those generally accepted by society. Some of these unfortunately may be *undetectable* that is to say although perfectly intelligent, unable to earn their own living. Others are the *creative* people, who as in the case of Van Gogh did many eccentric things but also many productive things—Van Gogh was gifted or cursed with an intense sensitivity. Lastly there are those who have what others regard as peculiar sexual habits. Of the first two classes nothing more need be said, and all that is necessary is to mention certain of the so-called sexual perversions. (When we say so-called the implication is not that none of these forms of behaviour is perverse but that some of them are carried out by otherwise quite ordinary people.) *Sadism* and *Masochism* refer to in the first place, pleasure in inflicting pain and in the second to receiving pain. The pleasure is sexual and it is incorrect to talk of cruelty in itself as sadism. Sadism is named after the Marquis de Sade who suffered from this perversion although he certainly did much less harm in his small way than numerous politicians or generals of our time, and masochism is named after the Austrian novelist Sacher Masoch who wrote books which although unpleasant were not notably more so than certain Sunday newspapers of today.

Masturbation is sexual self stimulation. Need less to say it produces no more physical harm than ordinary sexual intercourse—that is to say none at all, although some people have the strange belief that every act of intercourse weakens the body and it has even been believed that each act shortens life by a specific length of time. This is rather illogical in view of the fact that most of the famous rakes have been noted for their longevity. Masturbation is almost universal in infancy, adolescence or even in later life when other outlets are not available. It need only be a matter of concern (a) when it is chosen in preference to normal sexual activity or (b) when it is compulsive and excessive since then it is a sign, not of sexual desire but of severe underlying anxiety.

Homosexuality is as presumably most people now know an attraction between individuals of the same sex. Most people pass through a brief homosexual stage. Ordinarily this comes just before puberty when schoolgirls get crushes on older girls or teachers and schoolboys have similar feelings towards their heroes. The disposition however may be retained into adult life. Now days people take a much more tolerant view of homosexuality accepting that what adults do

(with consent) is their own business and that a male homosexual who seduces a boy under age should be treated in no way differently from the man who seduces an under age girl. Male homosexual practices are no longer an offence if committed in private between consenting adults. Female homosexual practices have never been an offence.

All that remains to be said is that many of these conditions are treatable or if not treatable so far as cure is concerned they can at least be relieved. The world is full of people who are different: there are those who are different in the right way who should take satisfaction from their achievements and those who are different in the wrong way who should seek expert advice. Since psychological treatment is time consuming it is not very easy to obtain it within the National Health Service although group treatment has simplified the problem. However any person with such difficulties would probably benefit from a discussion with his family doctor.

DISEASES OF THE SKIN

The skin in the course of development before birth is particularly closely associated with the nervous system. It is therefore not surprising that so many skin diseases are influenced by emotional states. Other causes of skin disease are infections, glandular disorders, vitamin deficiencies and the numerous conditions for which no cause has been discovered but which presumably are due to metabolic disorders.

One of the commonest skin symptoms is *itching* or *pruritus*. It may accompany many different general diseases for example diabetes and jaundice. It may also be troublesome during the menopause (the change of life in women) in old age or in nervous conditions. Sedatives and sex hormones sometimes help the itching during the menopause and there are ointments which may be useful.

Itching in the region of the anus and genital organs is relatively common. It may be caused by worms by irritating vaginal discharge or by sugar in the urine as in diabetes. The alteration in the normal bacteria of the bowel which follows treatment with various antibiotics also often causes anal pruritus and soreness. In many cases however the itching has some psychological cause. In treatment it is important to avoid ointments and creams which contain a local anesthetic because these substances can cause severe allergic reactions if used for longer than a few days and may thus make the condition much worse. Treatment with a local corticosteroid application is more effective and safer.

Parasites such as the *scabies* mite or *lice* can cause severe and persistent itching. The scabies mite is very small and since it burrows under the skin surface is unlikely to be seen. It is the cause of itching most commonly between the fingers and on the front of the wrists. The itching is worst when the body becomes heated as in bed. Treatment consists of painting the body from head to foot with benzyl benzoate application, followed the next day by a hot bath. Since scabies is contracted through close personal contact with an infested person it is often desirable for several or all members of a family to be treated at the same time even though only one of them may be affected. Lice are specialists: one type of which affects the scalp, another the body and a third the genital area. Head lice are destroyed by lethane body lice by D.D.T. (dicophane) powder and genital (pubic) lice by shaving off hair and washing. Obviously the clothes especially in the case of body lice should be disinfested either by the use of D.D.T. or if this is not available by using a hot iron over the seams which lice (for some inexplicable reason) seem to favour. Apart from the discomfort they cause lice are dangerous as potential carriers of typhus fever.

Baldness or *Alopecia* is a very common condition, as is manifested by the extraordinary number of preparations advertised as curing it. When

many preparations are offered for the treatment of one condition it is a fair judgment to assume that none of them is likely to be effective. There are in fact two types of baldness: one which is much the commoner is hereditary and cannot be influenced in the slightest by any treatment; the other *alopecia areata* is caused by nervous stress and would recover in most cases by itself whether one used a solution of soot and water or the most expensive hair food. There is no such thing as a hair food any more than there is such a thing as a nerve food and although it is probable that hair hygiene may delay baldness it certainly cannot prevent it. All hair tonics and foods are useless and their uselessness is only equalled by their costliness. Those who have lost their hair and find it growing again after using some alleged tonic are people who have had *alopecia areata* and whose hair would have grown back anyhow. In women the hair often thins out soon after a pregnancy but a few months later it usually returns to normal.

Seborrhoea is a condition in which there is over activity of the sebaceous glands. The most usual form it takes is *dandruff*. However it takes other forms and those who have dandruff may also have rashes on the face shoulders and chest. In these areas there is a patchy greasy and often itchy rash which does not clear up until the primary condition in the scalp is dealt with. The scalp should be washed with one of the modern sulphur containing shampoos at least twice a week and the affected parts on the face and chest can be dealt with by the use of a sulphur lotion (not on any account by greasy ointments). *Seborrhoea* is not in itself difficult to treat but since the condition depends on over secretion of sebum the skin lubricant treatment may have to be persisted in during the years of early adult hood when it is most active.

Erythema Intertrigo is quite simply the sort of irritation which occurs from excessive sweating under the armpits between the legs and under the breasts in women. All that need be done is to wash frequently and to dust the affected areas after washing with powder. This is the condition which in the tropics is known as prickly heat and elsewhere as a sweat rash. In some people *hyperhidrosis* or excessive sweating is a problem, especially when the sweating is accompanied with body odour—the sort of thing that, according to the advertisements even your best friends won't tell you. There is little need for anyone in these days to suffer in this way for the cosmetic firms have produced many highly efficient deodorants which not only control odour but also control the amount of sweating. Chlorophyll which has been much advertised as removing odours is effective when applied directly to surfaces which give off an unpleasant smell. It is however ineffective when taken by mouth, and does not prevent body odours. Stale sweat smells bad because it is decomposed by bacteria, and this type of body odour can be largely prevented by preparations containing a harmless antiseptic such as hexachlorophane and an antiperspirant such as aluminum chloride (see *Which* February 1960).

Erysipelas is an infection of the skin caused by the hemolytic streptococcus. It begins as a red, raised area anywhere on the body where the germs have been able to enter through a small crack or cut in the skin. The red area advances and spreads over the body until the disease is got under control. *Erysipelas* is very infectious and those who look after the patient should wash their hands thoroughly after contact. At one time the disease used to spread as an epidemic throughout the hospital wards but this is very rare nowadays. Treatment is of course, a matter for the doctor.

Chilblains are common in cold weather especially in those with poor circulation. Ordinarily they occur in the toes and fingers but may appear on the nose and ears. The part affected becomes swollen dusky and there is pain and itching sometimes leading to ulceration. Protection of the body especially the hands and feet from cold is the best and the only really effective way of preventing chilblains. Warm lined gloves

and footwear and warm stockings or trousers should be worn outdoors. Adequate heating of rooms is essential. A temperature between 18 and 21°C is recommended (65–78°F). Most tablets medicines ointments or creams for chilblains are useless. A skin affection caused by heat is rather grandiosely described as *erythema ab igne* and is frequently seen on the legs of ladies addicted to roasting their legs before the fire. It takes the form of red patches on the front of the legs and can be removed only by avoiding the cause.

Dermatitis means inflammation of the skin and therefore the word could be strictly speaking applied to any skin disease. In fact the term is used almost interchangeably with the term *eczema*. There are three main types of dermatitis or *eczema*. The first *primary irritant dermatitis* results from injury of the skin by some powerful chemical such as strong alkali or turpentine. The second *contact dermatitis* is due to sensitisation of the skin to some substance which is normally liable to cause this type of allergic sensitivity: examples are nickel (in jewellery and suspender buckles) epoxy resins rubber additives primulas and chrysanthemums and even ingredients of cosmetics. Contact dermatitis may continue for a long time even after the patient is no longer in contact with the offending material. The third type is often called *constitutional eczema*. Although the skin is apt to react adversely to various irritants and sensitizers the major part is played by the personality and there is often a history of *eczema* hay fever or asthma in the family. Treatment is more difficult but local corticosteroids and tar sedatives and psychological treatment can be of great help. Infantile *eczema* also belongs in this category but in most patients it disappears as the child grows up.

Impetigo is an infectious skin disease caused primarily by the streptococcus, but later often infected with staphylococci. It usually occurs on the face and takes the form of blisters filled with pus on a red base when the blisters burst their place is taken by yellow crusts. Impetigo is very infectious and easily spread by the fingers dirty towels or cloths therefore one of the first necessities is to prevent infection of others or reinfection of oneself by avoiding scratching and using a different towel each day which must on no account be used by anyone else. Treatment is simple with an antibacterial ointment so the main issue is prevention of contamination.

Sycosis or Barber's Rash occurs in men and is similarly treated.

Urticaria or *Nettle rash* is a familiar skin disease in which itching weals appear on the skin, usually for no obvious reason. It is not infectious and can be caused by nervous stress certain drugs, allergy to some foods or even exposure of the skin to cold. In some people it is possible to write on the skin with a fingernail the writing appears in the form of weals. This is known as *dermographism*. It occurs in many normal persons as well as in many patients with urticaria. The antihistamine drugs are the most useful in the treatment of urticaria. Urticaria swelling of the tongue or throat must however be relieved at once and is treated by an injection of adrenaline.

Acne or *Blackheads* is a condition found on the face and shoulders its appearance is so familiar that no description is necessary. Acne is one of those conditions which is the end result of many factors. There is first a greasy skin the result of glandular upset (which is why the disease usually occurs in adolescence). Secondly there is infection of the skin and thirdly there is blockage of the sebaceous ducts which ordinarily allow the grease from the skin to pass out on to the surface. Since the condition starts with excess secretion of grease ointments should never be used and probably the best applications are drying lotions containing some sulphur preparation which inhibits secretion of grease. The face should be frequently washed, and it is possible now to obtain detergent solutions which are both antiseptic and prevent grease formation. In severe cases ultraviolet ray treatment may be necessary.

Rosacea. As has already been implied elsewhere although the wages of sin may be extremely unpleasant the wages of extreme virtue may be no less troublesome. Thus *rosacea* in which the nose and cheeks become red and greasy and the skin coarsened occurs alike in chronic alcoholics and elderly ladies with no vices other than a preference for strong tea. Both cases are associated with indigestion since regrettable as it may seem, strong tea and alcohol are about equally liable to cause the gastritis which may be at the root of this complaint. However in many patients the chronic flushing is caused in other ways and psychological factors are important.

Lichen Planus is one of the numerous skin diseases which seem to be due to nervous states of tension. It may occur on any part of the body but is most common on the front of the forearms and legs. The rash takes the form of nodules which are lilac in colour and have a dent on the top when these disappear a stain is left behind. There is severe itching. Treatment is a matter for a doctor as it also is in the case of *psoriasis* a very common disease of largely unknown origin which is extremely resistant to treatment. It tends to run in families. It takes the form of slightly raised papules usually on the elbows and knees typically the papules are covered with dry silvery looking scales. Apart from the rash the patient is usually in perfectly good health and there is no itching. Many drugs have been used in *psoriasis* notably chrysarobin and while it is not difficult to cause the rash (which may occur anywhere on the body) to disappear in one area or even in all areas for a time it has a strong tendency to return.

Warts or Ferrucae are familiar enough. They are caused by a virus and are theoretically at least contagious (although having removed many warts the writer has never found them contagious). Most frequently they are found on the hands but may occur elsewhere. Treatment is best carried out by a doctor who will use a caustic or a caustic carbon dioxide frozen into snow. A curious feature of the common wart is that it can sometimes be caused to disappear by suggestion which is presumably why so many old wives charms are not necessarily without effect. Different altogether from the common wart is the *plantar wart* which occurs on the soles of the feet and often causes a good deal of discomfort. It is best dealt with by a chiropodist or in bad cases by a skin specialist since it is highly infectious.

Ichthyosis is a disorder of horn formation with which some unfortunate people are born. The oil and sweat-producing glands do not function well and the skin is dry and scaly like the skin of a fish. It is however possible to help the condition, which does not affect the general health by frequent alkaline baths to wash off the scales and the subsequent use of lanolin to replace the lacking oil. Large doses of vitamin A seem to help in some cases and there have been reports in the medical press of cases being helped by hypnosis this however is very much a matter for speculation.

Cancer, Rodent Ulcer and Cysts. Cancer of the skin occurs mostly in old people and takes the form of what is described as an *epithelioma*. It is most common on the face or hands and usually appears as a nodule which breaks down and produces an ulcer. The glands may later be affected but such cancers can almost invariably be cured unless a considerable time has elapsed during which they have been neglected. *Rodent ulcer* is a form of ulcer which appears on the inner corner of the eye or the side of the nose in old people. It does not spread over the body but acts by eating into the tissues in the area where it has started. X-ray or operation is necessary but the outlook is good. *Cysts* on the skin are due to blockage of the sebaceous glands. They may become very large, and are best removed as they may become infected. They do not turn into cancer and there is no such thing as male and female cysts. It does sometimes happen that moles, especially of the bluish black type, may become malignant, so it

is perhaps best to have them removed surgically when they exist. All moles which change in appearance or size should be at once referred to a doctor.

Skin Grafts

These are a very complex subject which can be only briefly discussed here. They are used basically for a number of conditions in which large areas of skin have been removed from the body as in burns or serious accidents. In other cases as in plastic surgery grafts may be used to make a new nose eyelids and so on. The following are the main types.

Pinch Grafts are small circular pieces of skin cut from some other part of the body. (The former method of using grafts from another person has been given up almost completely since such grafts—except in the case of identical twins—never take.) The small pieces are laid on the area without skin and gradually grow together. **Split thickness grafts** are grafts removed from another part of the body by an instrument known as a dermatome which cuts sections about 4 in by 8 in containing part of the deep layers of the skin.

In **Full thickness Grafts** on the other hand the whole thickness of the skin is removed from elsewhere and applied to an area which has to bear friction or heavy weights such as the hand or the foot. Lastly and this is largely used in plastic surgery there is the *Pedicle graft* which unfortunately although it is certainly the most exciting type is rather difficult to describe. Briefly if one for example wants to make a new nose one cuts an area of skin and underlying fat about 2 in. wide and 5 or 6 in. long in the abdomen. One end however remains attached so that it gets adequate blood supply. The problem is how to get this tissue to the nose and this is done by a complicated process of leap frog. First the free end of the graft is attached to the forearm whilst its root remains in the original site and when it begins to grow and get its blood supply from the arm the original root is cut. So we now have a sausage of tissue attached to the arm. The arm is then lifted to the face and kept firmly in position there until the new free part becomes attached. It is then detached from the arm modelled to the correct shape and grows where the nose used to be!

THE RHEUMATIC DISEASES

The main rheumatic diseases (or so they are described although they seem to have little relationship one with the other) are *rheumatic fever* the acute form which has already been dealt with (P28), *chorea* or rheumatism of the nervous system, also mentioned (P49), *rheumatoid arthritis*, *osteoarthritis* and *gout*. The only thing these diseases seem to have in common is that most seem to be associated with the connective tissues muscles or joints—thus, of course, with the single exception of *chorea*. Apart from this there is very little similarity.

Rheumatoid arthritis often starts without evident cause in early adult life and affects the small joints of the fingers and toes causing swelling and pain. No infective process has been discovered, yet the disease goes on and on, sometimes better sometimes worse. It is (and this is all one can say) a disease commoner in women, commoner in temperate climates commoner following emotional stress. Although, as we have seen, *rheumatoid arthritis* is a disease characterised by frequent remissions, it takes a considerable time to burn itself out. The most likely explanation for its occurrence is that stress reactions act on the suprarenal glands and the secretion of cortisone is inadequate to play its usual part in preventing the body from responding too severely to injury. However the injection of cortisone has proved on the whole less useful than might have been expected and there is little reason to suppose that in most cases it is any better than aspirin.

Osteoarthritis is essentially a degenerative disease of old people. The bones affected are ordinarily the larger joints—the shoulders, the hips, or the spine. There is no disease in the ordinary sense and essentially what has happened is that these joints have got old, and the bone has overgrown so that movement is less simple than it once was. Osteoarthritis is not curable but can be relieved by drugs and physiotherapy.

Gout so far as one knows has nothing at all to do with rheumatism. It is a metabolic disease caused by the inability of the body to deal with certain protein breakdown substances such as uric acid.

DISEASES OF THE EYE

The Eye

The eye is frequently compared to a camera and in a general sort of way there is some resemblance. The eyeball consists of 3 coats within which are contained the refraction media. (1) The outermost layer, the main support of the eyeball comprising the sclera (opaque) and the cornea (transparent covering the front of the eyeball). The conjunctiva (the part which gets inflamed when you get germs or dust on the surface of the eye) is a thin protective membrane covering the sclera and doubles back to line the inside of the upper and lower lids. It stops at the junction of the sclera and cornea. (2) The middle layer containing many blood vessels which forms the choroid and in front the iris (the coloured part of the eye). The muscle in the iris enables its central aperture, the pupil to contract in bright light and to dilate in dim light. (3) The innermost layer of nervous tissue, the retina. The retina contains the expanded termination of the optic nerve which is part of the brain. Behind the iris is the lens, which is controlled by a series of muscles which increase or diminish its curvature and thus produce according to the nearness or distance of the object a clear picture on the retina. Some of these parts may of course be affected by disease. Here we shall deal only with a few of the more common diseases.

Blepharitis is an infection of the eyelids which is easily recognisable from the red, sore appearance at the margins, the formation of crusts and the falling out of the eyelashes. If it has just developed, an attempt may be made to treat it at home with hot bathing and the so-called Golden Eye Ointment, but *blepharitis* is liable to become a chronic disease and it is wiser to see a doctor. Penicillin cream or ointment can cure the disease but must never be used save under medical advice, allergy to penicillin is commoner in the eyes than anywhere else and in some cases patients have lost their sight through its use in this way.

Conjunctivitis is the result of infection of the conjunctiva, and the symptoms are the familiar ones of a feeling as if some grit had got into the eye, running from the eye and frequently gummy together eyelids in the morning. In some cases it can be treated by hot bathing and eye baths with one of the proprietary lotions on the market, but it is much wiser to see your doctor, who can supply much more effective remedies and may save you a lot of unnecessary discomfort.

Other Eye Diseases. We can only mention briefly *keratitis* inflammation of the cornea, *iritis* inflammation of the iris and *glaucoma*. These are all potentially serious diseases and should not be diagnosed or treated by the layman. Glaucoma in particular may lead to blindness if help is not sought in time. If there is redness and congestion over the eye, dimness of vision, severe pain (as contrasted with the irritation caused by conjunctivitis) and perhaps even vomiting the doctor must be called immediately.

The main disease of the lens is *cataract* in which the lens becomes opaque and varying degrees of blindness result. Ordinarily cataract is a condition found in people after middle age but sometimes it is found in children at birth. The treatment is by operation—one which has been

carried out for centuries—in which the opaque lens is removed. The patient thereafter has to wear glasses but the vast majority of patients obtain good vision.

In *retinitis* however where the screen at the back of the eye is affected the general outlook is more serious. This is because whereas cataract is a localised disease retinitis is often signifies some bodily illness—infection, hardening of the arteries leading to hemorrhage, diabetes or kidney disorders. Sometimes the retina becomes detached leading to blindness. As has been suggested above except in very minor conditions such as styas (a localised infection treated in the same way as blepharitis) or conjunctivitis the doctor should always be consulted. He should be consulted too when a foreign body gets into the eye unless it can be removed by very gentle manipulation with a handkerchief for it must be remembered that such poking about on the surface of the eye may do much more harm than the original condition. So if a couple of minutes fail to remove the grit, give up and go to the surgery.

DISEASES OF WOMEN

The *internal sexual organs* of a woman like the urinary system can best be described as shaped like a capital Y. At the tips of the arms of the Y are the female sex glands the ovaries, the two arms running downwards are the Fallopian tubes, the point where the arms meet is the womb or uterus, the single leg of the Y is the vagina. These are the *primary sexual organs* of a woman and they undergo regular cyclical changes in response to the control exercised over them by the pituitary gland situated in the base of the skull. This control is mediated by chemical messengers (hormones) secreted into the circulation. The ovaries also secrete hormones, oestrogen and progesterone and a delicate hormonal balance is maintained between the pituitary gland and the ovaries. Each month an egg cell (ovum) matures and is released from the ovary usually midway between two menstrual periods, the ovum is waited along the Fallopian tubes by waves of contraction and if fertilised embeds in the lining of the uterus which has been conditioned to nourish it by the ovarian hormones. If it is not fertilised the ovum escapes from the uterus, altered hormone levels then cause the lining of the uterus to be shed (this is menstruation) usually about 14 days after ovulation. After menstruation a new cycle begins, another ovum matures and a fresh lining grows in the uterus. These cyclical changes recur from puberty to the menopause. Menstruation does not occur during pregnancy of which a missed period is often the first sign. However women do miss periods even though they are not pregnant and this usually means that some minor and temporary change has occurred in the hormone balance. If three consecutive periods are missed it is wise to consult a doctor.

The *breasts* are called *secondary sexual organs* and are also under the influence of the ovarian hormones. Two conditions which need treatment are *mastitis* and *cancer of the breast*, both of which are characterised by lumps within the breast tissue. Mastitis may be uncomfortable but is not dangerous and can be treated medically whereas cancer is more serious. The distinction between mastitis and cancer can only be made by a doctor and any woman who discovers a lump in her breast must seek medical aid at once.

Abscesses also occur in the breast, nearly always when the mother is feeding her child. Here again a lump appears, the breast becomes red and very tender and the woman may be feverish. Treatment with antibiotics is sometimes successful especially if the mother consults her doctor quickly otherwise treatment is by a small operation.

The Ovaries. The two commonest diseases of the ovaries are cysts and disorders arising from hormonal imbalance. The symptoms of ovarian disease are usually abdominal or low back

pains and heavy and painful loss during the periods which may become irregular. These signs should be taken as a warning to consult a doctor

The Fallopian Tubes Infection of the Fallopian tubes is called salpingitis. The membrane lining the tubes is continuous with the lining of the uterus hence an infection is rarely confined to a circumscribed area in either the tubes or the uterus and pelvic inflammatory disease is a better name for this condition. Pelvic inflammatory disease often follows an abortion or childbirth where part of the afterbirth (placenta) has been retained or can spread from an infection in a nearby organ for example the appendix. Infection is sometimes conveyed by the blood from another septic source in the body. The gonococcus is another cause of infection. The disease is characterised by pain and tenderness in the lower part of the abdomen accompanied by fever, general malaise and frequently (but not invariably) a vaginal discharge. The treatment of pelvic inflammatory disease is usually medical and is the same irrespective of the primary site of infection. Before the introduction of antibiotics the disease often became chronic and the Fallopian tubes were frequently blocked by a catarrhsing scar a cause of subsequent sterility.

The Uterus This is a hollow muscular organ and both its musculature and its lining membrane can be the site of disease. *Fibroids* are non malignant muscular tumours which develop in many women. The main symptom is a heavy menstrual loss and surgical removal of the uterus (hysterectomy) is often necessary. This is a major operation but modern anaesthesia and operative techniques minimise the discomfort. Hysterectomy does not impair sexual pleasure but no more babies can be conceived. Infection of the lining of the uterus is usually part of a generalised pelvic inflammatory disease (see Fallopian tubes).

Cancer of the Uterus and Cervical Smears The uterus is pear shaped and consists of a body and neck. The wide end is uppermost (the body) and the narrow neck (cervix) projects into the top of the vagina. Cancer of the cervix is commonest in middle aged women who have married young and have had a large family. Cancer of the body of the uterus usually occurs after the menopause and is most common in childless women. The symptoms are variable and it is sufficient to emphasise that any woman who has unexpected bleeding especially after intercourse whether her periods have stopped or not must see her doctor at once. The treatment depends on individual circumstances but is usually by operation. It is now possible to detect cancer of the cervix long before symptoms develop and at a stage when the disease can be eradicated by a relatively small operation. This early detection has been made possible by the development of exfoliative cytology. Cells taken from the cervix (without discomfort to the woman) are examined under a microscope. This test is popularly known as the cancer test or cervical smear. A cervical smear is often taken as part of the routine gynaecological examination by consultants, general practitioners, and family planning doctors and is also being included in some population screening programmes. It is a big step forward in preventive medicine and may ultimately solve the problem of cancer of the cervix. Every woman between the ages of 25 and 60 should seize any chance to have this test done.

Prolapse means a sagging down of the uterus into the vagina and the cervix may even appear at the outside. It is a result of frequent childbirth and laxness of the ligaments which support the uterus. Weakness of the vaginal walls often occurs at the same time. The symptoms of uterine prolapse are low back pain and a heavy dragging feeling in the lower abdomen. These are often overshadowed by the distressingly embarrassing incontinence which results from lax vaginal walls. The stress of only a sneeze, a cough, or a giggle often causes the involuntary escape of urine. The cure is operative and very rewarding.

Dysmenorrhoea or pain with the periods is very common and most women experience this symptom at some time or another. Very often a girl's first periods are troublefree but dysmenorrhoea develops after a year or two. This suggests that a psychological element is involved. Dysmenorrhoea is a symptom which has many varying causes and the sensible thing to do if pain is troublesome is to see a doctor.

Amenorrhoea means stopping of the periods in a young woman. It may signify pregnancy or glandular disease, or it can be purely psychological.

Abortion or its more acceptable name miscarriage describes the spontaneous or induced termination of a pregnancy before the foetus (baby) is able to survive. A baby cannot live unless it is born after the twenty-eighth week of pregnancy though many infants born at this time die. The two main symptoms of abortion are bleeding and abdominal pain. Any bleeding occurring during pregnancy ought to be reported at once. Pain starts in the back and lower abdomen and is usually spasmodic in character and like colic it works up to a peak and then temporarily passes off. Any pregnant woman with pain and bleeding should go to bed at once and send for her doctor. When doctors are convinced that a pregnancy should be terminated then an abortion by safe surgical means may be performed in hospital.

CONTRACEPTION

If a couple intends to practice birth control expert advice should be obtained from their family doctor or family planning clinic. The matter of whether or not a baby is born is too important to leave to chance. The method chosen must be effective as well as acceptable to the couple concerned and the extent of the choice only emphasises the fact that the ideal contraceptive which is best for every couple at all times has yet to be discovered. The only method which is 100 per cent reliable is abstinence. If the male seed (sperm) fertilises the female seed (ovum) then pregnancy results. Contraception is only effective if this union is prevented. A couple can achieve a measure of contraception without the help of pills or appliances if the husband practices *coitus interruptus* or they rely on the wife's safe period. *Coitus interruptus* (when the man withdraws before emission occurs) is a thoroughly unreliable method which often leads to psychological difficulties in both partners. The rhythm or safe period method relies on estimating the time of ovulation and abstaining from intercourse during this time. This is at best unreliable though its effectiveness can be improved by keeping careful records of the body temperature on waking each morning as the temperature rises once ovulation has occurred. The interpretation of these temperature records needs care and couples who must rely on this method can obtain expert advice from, for example, The Catholic Marriage Advisory Council or a family planning clinic. *Barrier methods* prevent the sperm from reaching the ovum and can be used by the man (sheath or condom) or woman (cap or diaphragm); the reliability of the barrier is greatly increased if it is used in conjunction with a spermicidal cream, jelly or pessary. A great many women have found that the *oral contraceptive pill* is ideal for their needs; it is the most aesthetic means of contraception and offers the most complete protection against pregnancy. Oral contraceptive pills contain chemical substances (oestrogen and progestagen) which replace the hormones normally released from the ovary while an ovum is developing. Ovulation does not occur and without an ovum there can be no pregnancy. Pills must be taken strictly as directed as the dose is the lowest that will provide effective contraception and missing a tablet may result in pregnancy. Side effects sometimes occur (for example nausea, breast discomfort, headaches) but usually decrease after a few cycles of medication. Newspaper reports of the deaths of young women taking the pill have caused widespread concern. These tragedies

have followed blockage of a blood vessel (by thrombosis or embolism) and have been carefully investigated and the conclusions are that the number of such deaths is small and does not differ from the number which would probably have occurred in any case. No satisfactory pill for a man has yet been developed. In the newest method of contraception a small plastic *intra uterine device* (loop bow or coil) is inserted into the womb. Once inserted it can be forgotten, a tremendous advantage to many different peoples and societies. It is not as effective as the pill

but is more satisfactory than barrier methods. This intra uterine device is not suitable for all women and is usually not recommended to women who have borne no children or who have very heavy periods. However careful selection of suitable women has resulted in a high proportion of satisfied users. The search for the ideal contraceptive continues.

Vasectomy (a form of sterilisation) may now be performed under the health service on a husband in the interests of the health of either husband or wife.

PART III SPECIAL TOPICS

INFANTILE UNDERNUTRITION AND THE BRAIN

In the last few years a great deal of attention has been given to the problem of whether malnutrition in early life can result in damage to the developing brain in such a way as to leave permanent deficits in intellectual capacity persisting into adult life.

This formulation of the problem is of course very much influenced by an increasing awareness of the prevalence under normal circumstances of widespread infantile malnutrition throughout the underprivileged world, a situation which is thrown into sharp relief by man made or natural disaster. Community catastrophes reduce still further the nutritional intake of children who are already struggling for existence below the borderline of minimum requirements. Most people still do not appreciate that the pictures of starving children in disturbed areas recently given so much publicity by newspapers and television could easily have been taken in any of the other vast territories where life is still considered normal and undisturbed.

From the limited point of view of scientific investigation the question is whether physical restriction of supplies can affect the physical development of the brain in a lasting manner and whether this in turn can lead to deleterious effects on mental function.

For reasons which will be elaborated there are several classes of children in our own more privileged communities whose brains may be equally at risk from perinatal growth restriction without severe malnutrition.

Two Lines of Approach

Two main lines of investigation are being followed in current research. At first sight it may not seem difficult to answer the question by making observations on grown up people in underprivileged communities whose infancy was affected by severe nutritional deprivation. In practice however even if one could collect a group of people whose personal histories were so well documented as to comprise a scientifically acceptable sample, even if one could find a well fed control group in the same community with comparable environmental influences on their development and even if it could be satisfactorily demonstrated that the previously undernourished people were indeed at an intellectual disadvantage compared with the controls it would still need to be shown that the mental deficits were a direct result of undernutrition restricting the physical development of the brain. And to demonstrate that would assume a knowledge which we do not possess of the connection if any between the physical state of the brain and its intellectual function. There might of course be innumerable other possible connections between the early undernutrition and the subsequent intellectual deficit such as an inherited constitutional dimness in these particular members of the community which would itself also make them differentially vulnerable to all the ills of poverty including infective disease, as well as undernutrition.

A second line of approach to the question attempts to reduce some of the complexities by controlled experiments using animals whose normal growth programme is measured in weeks rather than years and in whom a closer homogeneity of environmental conditions and ultimate

products can probably be obtained. It is much more acceptable to impose experimental growth controlling nutritional regimes on rats and in particular they can be killed to a pre-designed programme and the physical state of their brains examined. However the behavioural correlations are at least as difficult to determine in rats as in humans and digging out the brain and the need to mince it up make longitudinal study of individual animals more difficult. And finally from the human point of view we would still be left with the question of how meaningful would be an extrapolation from rats to humans.

Having attempted to show that our original question is scarcely amenable to investigation and therefore scarcely a question we will now outline the manner in which we have begun to try to answer it at least in respect of the physical effects which can be produced on the physical development and ultimate state of the physical brain. It can now be shown that permanent deficits can be produced in the adult brain by quite mild restrictions of bodily growth provided these are imposed at certain critical limited times in early life.

Just as the body itself does not grow at a uniform rate at all times but undergoes growth spurts at certain stages so the brain passes through a major growth spurt during which it is growing very fast indeed. The brain growth spurt occurs in all species in advance of the general bodily growth spurt. In our own human species this period extends from the last weeks of gestation through the first several months of postnatal life.

The Hypothesis

The hypothesis which is being investigated proposes that brain development is likely to be most vulnerable to restriction at the time of its most rapid growth and that restrictions imposed at this time are likely to be to some extent irrecoverable. A corollary to the hypothesis is that the farther away from the period of most rapid growth the more severe will have to be the deprivation to produce a comparable effect until in the adult there may be no effect on the physical brain whatever even from the most severe starvation unto death.

To take the last point first it is cheating to include the postulate of adult brain invulnerability in a predictive hypothesis since it has been a partly established fact for at least one century that adult brain weight is unaffected by starvation. This is true even if the individual is slowly starved to death over a long period and his body and other organ weights are reduced to half their normal values. However it has probably always been suspected that at least some of the metabolic substances to be found in the adult brain would be diminished or seriously distorted by starvation just as they are in (for example) the liver. Surprisingly it has recently been established that even the detailed chemical composition of the brain is virtually unaffected by adult starvation, just as is its fresh weight and this is a very striking example of the old nutritionist's doctrine of 'brain sparing'. Such is certainly not the case with the developing brain which as will be seen, can suffer quite striking reductions in its chemical and cellular composition as a result of quite mild growth retardation, much milder than the severe starvation imposed on the adult with impunity. Indeed it is sufficient to rear suckling rats in rather large

litters to produce irrecoverable deficits in brain size, numbers of cells, and degree of myelina, on some of the evidence for this will be described.

Returning to our hypothesis that lasting effects may be produced in the brain by early growth restriction, there are several theoretical reasons which lend it support. For example, the brain is a tissue in which the adult number of unit cells or neurons is achieved quite early. By twenty-five weeks of gestation you probably have as many nerve cells as you will ever have and these cells are incapable of multiplication or repair after this stage. So the theoretical possibility is easy to accept that early interference at the time they are laid down and growing will have permanent effects. Similarly, there is metabolic stability in much if not all of the myelin substance. Myelin is the material derived during the brain growth spurt from the other brain cells which wrap an insulating sheath around the nerve fibres. The molecules of which this sheath are made do not turn over metabolically throughout life as many other body constituents do. Once laid down in sheath structure during the brain growth spurt, there they probably remain throughout life. It is the inability of myelin to regenerate after injury of the central nervous system which is responsible for failures of recovery in certain chronic human neurological disease. Again it is not difficult to accept the proposition that early restriction of myelin synthesis will lead to irrecoverable deficits in the adult brain.

Experimentally Observed Facts

Let us now leave theoretical speculation and turn to experimentally observed fact. We know that the principal components of the brain growth spurt are:

- (1) An increase in the size and number of nerve fibres and other processes growing out of the already established nerve cells and the consequent vast increase in the numbers of functional connections between them.
- (2) An almost explosive multiplication of another important brain cell type—the oligodendroglia. These are the cells which manufacture the myelin sheaths.
- (3) The process of myelination involving the synthesis of myelin materials by the oligodendroglia and the building of these materials into the insulating myelin sheaths.

We have a convenient way of measuring the second and third of these processes chemically. This is necessary because it would be quite impracticable to count the astronomical numbers of structures involved by any morphological technique. For example, it can be assumed that all the cells contain the same amount of DNA in their nucleus and therefore a chemical estimation of the increasing amount of DNA in the tissue is an index of cell multiplication. Similarly an estimation of the increasing amount of fatty myelin is possible by estimating a representative myelin fat chemically. Since both nuclear DNA and myelin lipid are metabolically stable, an estimation of each will always represent the extent of development which each has undergone in the brain. It is by such comparatively crude techniques as these that lasting physical effects on the developing brain can be quantitatively measured.

The use of small laboratory animals is thought to be valid at this stage of the investigation. Their brains consist of anatomical units identical with the human and in their growth and development they pass through a similar sequence of changes. The main difference from the human apart from the complexity of the eventual product is the timing of their brain growth spurts in relation to birth. Thus the period of fastest growth in the rat brain is entirely postnatal and is encompassed by the normal suckling period. The brain growth spurt in the guinea pig is before birth, while that of the domestic pig like our own occurs either side of birth. Valid extrapolations from one species to another must therefore take this difference of timing into account.

The rat is a convenient species, since manipulations of growth rate can easily be accomplished

during the suckling period within which the entire brain growth spurt occurs. In one experimental design two litters of rats born on the same day are taken from their mothers on that day and placed together in a basin. They are then mixed together. Three are awarded at random to one mother and the balance of fifteen to twenty are given to the other. They are then left to rear their artificially created families and at the time of weaning at twenty-one days it is found that the privileged three from the small family are about twice the size of the others. An interesting thing is that their smaller contemporaries from the large litters remain small for the rest of their lives even when they are weaned to an *ad libitum* diet. Their growth programme has been permanently altered, but this can only be accomplished by restriction at such an early stage. Restriction at a later stage of growth is much more recoverable and in the mature animal it is usually completely so.

The opportunity now arises of examining the brains of animals pursuing these different growth trajectories. It is also easy to design experiments using different permutations and combinations of periods of growth restriction. For example, large and small weanling animals from small and large litters can both be weaned on to a deficient diet so that their growth is similarly depressed for some weeks after weaning. They are then released to an adequate diet. These two groups are apparently identically deprived at the end of the further period of undernutrition. However, one group has grown its brain under optimal early conditions whereas the other has been restricted at the time of brain growth. It is found that only the early restricted group like all animals suckled in larger litters have permanent deficits in brain size and composition resisting all attempts at rehabilitation.

It is important to appreciate that the mature products of early undernutrition which show these lasting deficits have not been severely underfed by being in a large litter. They show no signs of chemical malnutrition at the time and are not visibly distinguishable from animals at the lower end of the normal range. Nevertheless traces or the experience persist in the brain as in the body in marked contrast to the nil effect of severe starvation even to death on the adult brain.

The persisting deficits in the brain which have so far been discovered are of three main types:

- (1) The weight of the brain is permanently less.
- (2) The total number of brain cells is permanently less to the extent of between 10% and 20%.
- (3) The degree of myelination as determined by estimating myelin lipid per unit weight is permanently less. This latter case is an example of a deficit which is greater than and independent of the deficit in brain weight.

The significance of these findings is difficult to assess. Brain weight is dominated by body size during normal growth although the relationship is not a linear one. It is doubtful if a small brain is any real handicap provided its size matches the size of the body. Similarly the deficit in cell numbers may simply reflect the reduction in brain size although we would need to know which cells are missing before being sure and this we do not yet completely know. Thus the most significant finding so far may be the reduction in myelin which is independent of the brain size. Its significance is not necessarily due to the failure to complete the process of myelination since even this may not itself matter. In the present state of ignorance we prefer to consider it simply as a demonstration that this kind of permanent deficit can be produced in developing brain provided the deprivation is correctly timed to coincide with the brain's growth spurt and thus there may be other similar important deficits which we have not looked for yet.

Further powerful support for the hypothesis comes from the recent finding that of all the regions of the brain the cerebellum is the most severely affected in the experimental conditions which have been described. Indeed the main

brunt of the ultimate cell deficit is borne by the cerebellum, a comparatively small region which in the adult contains as many cells as the rest of the brain put together. Now it has been found in humans as in animals that this is a part of the brain which grows at an immensely faster rate than any other at the time of the growth spurt. It is therefore reasonable to predict on the basis of our hypothesis that if the growth of the whole brain be restricted at this time it should be the cerebellum which is hardest hit and such is indeed the case in experimental animals. Furthermore there is evidence that in these animals there is a detectable impairment specifically of cerebellar function. They are not able to achieve the same fine motor co-ordination achieved by normal controls.

It can now be claimed that considerable evidence is beginning to accumulate in support of our hypothesis that the brain growth spurt constitutes a particularly vulnerable period to growth restriction to the permanent detriment of the brain. If this be true and if the physical deficits achieved have any functional significance it remains to consider which human infants will be comparably at risk?

Conclusion

Unfortunately before we can guess at the answer we need to know the timing of the human brain growth spurt more precisely. Very little reliable information is available about the changing rate of human brain growth even in terms of whole brain weight. Useful information about the changing composition of human brain is only just coming to hand. From this we are able to say that the vulnerable period probably extends from about the thirtieth week of gestation throughout the first several months of life. If this in turn be true there are likely to be four main categories of human babies at risk.

(1) Severely underfed babies in underprivileged communities often also born of underfed mothers.

(2) Premature babies in our own community who are born at the very time which is most important for brain growth. Premature babies have to put up with a paediatrician instead of a placenta and he is not as good.

(3) Babies whose rate of intrauterine growth has been retarded and who are consequently born small for their gestational age. These small for dates babies comprise about one third of all babies of low birth weight.

(4) Babies whose developmental progress has for any other reason been impeded at this vulnerable time.

There is some evidence already that children from all these groups are somewhat less well endowed in later life though it must be repeatedly and firmly stressed that we are a very long way yet from proving the case.

SLEEPING AND DREAMING

An alien from some distant planet where biological life had never appeared might be surprised at the strange goings on he found on earth. He would see creatures of a great variety of shapes and sizes some cumbersome and armoured, some light and streamlined, others equipped with weapons for biting and tearing all chasing around trying to eat each other. He would conclude that life on earth was very dangerous but before going home he might notice a characteristic habit of these creatures seemingly at odds with the relentless duel they appeared to be engaged in. Quite frequently they would drop their neurotic alertness and almost incredibly lapse into a period of quiet with sense organs damped down, muscles inactive and worst of all their control centres seemingly switched off.

At this point the alien might decide that beings on such a planet which so carelessly let their essential defences drop didn't deserve to survive long and assume that this dangerous switch

off probably signalled the onset of some internal process not obvious to the outside observer which must be of tremendous importance to the creature's well being. His final surprise might come when he tried to ask the most intelligent of the animals what it was that was so important and found that they simply didn't know.

And this happens to be the truth for Man has made amazingly little headway into understanding sleep (which is of course the switch off an alien would have observed) although taken on average he devotes one third of his life to it. No doubt this is because sleep by virtue of its own special properties resists introspection—we cannot study it in ourselves without disturbing it. Furthermore it is a period when *nothing* seems to be happening: barren of thought and memory and yet inherently strange and enveloped in mysteries to which Man has frequently tried to provide answers. In this article we will look at some of these answers, note their general inadequacy and consider some new facts and a fresh approach which suggests that one of the main mysteries may be in the process of being unravelled.

Broadly speaking the various approaches attempting to explain sleep (and of course the dream) fall into three main groups that the writer has called (1) The Commonsense, (2) The Fantastic and (3) The Psychoanalytic.

The Commonsense

This theory states that the sole or principal reason for sleeping is to allow us to rest and alas for simplicity's sake it just doesn't happen to be correct. True there is something very tempting in the idea—after all we do switch into sleep after a period of feeling tired, and wake in the morning with this feeling altered. What more reasonable than to assume that the point of sleep was to rest the body after the doings of the day? The trouble is that from a physiological point of view sleep is *not* necessary to rest tired muscles and aching bones—a period of relaxation in an arm chair or stretched out on a bed *without* unconsciousness intervening is quite sufficient to allow the body's physical functions to return to their normal state. In fact during sleep the body engages in a series of postural shifts evidently geared to preventing the musculature seizing up through disuse. Perhaps then it is not physical but *mental* rest that is served by sleep.

The brain is the most important organ in the body working away all day thinking, learning etc. Should it not have a period of inactivity which ought to be accompanied by a period of unconsciousness or switch off? Unfortunately for this hypothesis the data from electroencephalography (recording the brain's internal activity by electrodes attached to the scalp) reveal that while there is indeed a significant and very interesting change in the nature of these electrical rhythms during sleep—notably from fast low amplitude to slow high amplitude firing—there is no suggestion that very much less is going on. The picture is not one of a run-down of activity but rather of a shift to activity of a different kind.

So much for the simple commonsense approach—in which incidentally dreams are looked on as nothing more than a kind of mistake or error in the system something to be avoided if a good night's sleep is to be had. We do not sleep simply in order to rest (which is not to say of course that some rest will not come with sleep).

The Fantastic.

This is the oldest view of all. In many parts of the world it is still the *only* view and while even in our own society large numbers of educated people still believe it it is really built on an out of date fantasy view of the universe. For this reason we call it 'The Fantastic'. It has as its main thesis the belief that human beings consist essentially of two distinct parts—the body which follows the laws of the physical universe and the mind, soul or spirit which is immaterial. During sleep and in certain other states, this mind or soul may escape the confines of its host body and the normal boundaries of space and time, to roam more or less at will, visiting Australia as easily as crossing a road, and popping into the

future for news of the Derby or of the death of a close relation.

Put this way the theory sounds silly rather than just fantastic, but this is not really an unfair representation of a very widely held point of view. The temptation to see sleep as the state of a body with some very important component missing must have been considerable to early philosophers who on kicking the body and finding signs of the spirit's return might then ask the individual where he had been. The reported dream would then be taken as a genuine account of a real experience. For dreams by this theory are in part real happenings, a hint of the essential spiritual nature of man and his ability to transcend space and time when the links with the material world are broken.

Support for this point of view comes from the dogma of orthodox religions which say that the soul of man is the true reality and more enticingly from the strange data of psychical research which nowadays is called parapsychology (338). The Library of the Society for Psychical Research in Kensington London has numerous authentic accounts of dream visitations from dead relatives to avert pre-visions of disasters in the future. In the 19th cent. Myers and Gurney pooled masses of these accounts into the enormously interesting volume *Phantasms of the Living* which would be one of the most important books ever published if one twentieth of its contents were true. More recently the mathematician J. W. Dunne claimed in his strange work, *An Experiment with Time* that dreams definitely provided a mirror into the future, a kind of time telescope which anyone could learn to operate. Today the beliefs of Myers, Gurney and Dunne seem less acceptable and the evidence for telepathy (343) patiently gathered by Rhine and co-workers two decades ago now carries less weight than ever among scientists and philosophers.

The cause of this is tied up with the decline in religious belief and the steady advance of scientific knowledge—both developments which make the

Fantastic view of sleeping and dreaming progressively less acceptable to most people.

The Psychoanalytic

The contribution of psychoanalytic theory to an understanding of the mind and its complex rules has been greatly over stressed and also greatly underplayed. In fact the single insight of the unconscious nature of many of our thought processes and their very real power in determining our behaviour is one of the most important concepts in psychology—or even in science for that matter. The psychoanalytic view of dreams has much to commend it and in simplified form goes as follows. Man is an animal with animal drives, emotions and needs. Society in exchange for protecting him requires him to obey certain rules many of which conflict drastically with his natural inclinations. These dynamic forces though they may be denied by the individual at a conscious level are merely repressed and retain latent psychic power in the inner rooms of the mind. During sleep with the force of the social censor diminished these drives and conflicts burst forth in the form of dreams. Mostly the dream itself is then subject to further repression, thus neatly accounting for the odd tendency we have all noticed to forget our dreams almost immediately we experience them.

Now the strength of this theory is arguable and the role of the dream in psychotherapy as a guide to the analyst in deciding the patient's *real* as opposed to his declared problems has proved dramatically fruitful in some cases. The real trouble of course is the pretence lately being abandoned that this provides a truly comprehensive theory of dreams—a pretence which has led to some awkward questions being asked and some unsatisfactory answers given.

To take a point most of us have had dreams in which the subject matter seems devoid of any significance in the psychoanalytic sense. To most analysts this kind of remark is anathema—the truth is they say that the real nature of the dream is so appalling or of so revolutionary a nature that it cannot even be *dreamt* in its raw form and must therefore be disguised lest it awake the dreamer. With this escape clause an unshakable, though

highly unsatisfactory comprehensive theory is possible in which all obvious dreams are obvious and those which are not are disguised.

This of course means that *any* dream can be interpreted in more or less *any* way to suit the interpreter's particular bias and has robbed the psychoanalytic approach of much of its original power. Although it was exceedingly fashionable at one time the psychoanalytic theory of dreams is not and is unlikely to become a comprehensive one.

Sleep Deprivation

Though a fair bit was known about the mechanics of sleep—blood pressure falls, temperature falls etc.—scientists seemed until quite recently to be getting nowhere in their quest to find the principal reason for sleep. One of the most persistent lines of approach (and one of the least fruitful as it turned out) was the hunt for specific toxins or poisons supposed to accumulate in the body during the day and requiring sleep to eliminate them. The hypnotoxin when found would presumably trigger sleep when a sufficient quantity had built up in the body.

Studies of people and animals deprived of sleep for varying periods made it quite clear that sleep was not just a bad habit, wasteful of time and fraught with danger but an absolute necessity for sanity and life itself. Most of the higher animals die if deprived of sleep for periods of a week or so showing en route signs of excitability and mania. Humans if the anecdotal evidence of mediaeval Chinese torture chambers is reliable die after a period as short as ten days again showing signs of madness prior to death.

The U.S.A. holds most records for prolonged sleep deprivation of which one of the best documented is that of Peter Tripp, a 32 year old disc jockey who stayed awake for over eight days in the window of a store in Times Square in 1959. Tripp suffered a three month depression to follow his record which has since been broken by another disc jockey Charles Christensen of radio station KMMN in California who managed a stretch under medical supervision of 11 days 18 hours in the summer of 1968. All who have subjected themselves to prolonged sleeplessness are united in stating that the process is very unpleasant and rich in hallucinatory adventure—a fact to bear in mind when considering the meaning of the exciting experiments which first began appearing in psychological journals in the 1950s.

In 1952 Eugene Aserinsky a Ph.D. student in the Physiology Department of the University of Chicago noticed that babies spent much of their sleeping time making rhythmic bursts of eye movements which could only be observed through the closed lids. He and the distinguished physiologist Professor Nathaniel Kleitman who had been studying sleep and dreams for years then checked with adult sleepers only to find a similar pattern. This observation suggested an interesting experiment—wake up the sleeper during an eye movement burst and see what he reports. This was carried out with the discovery that people woken during these R.E.M. (rapid eye movement) periods stated that they had been dreaming while others woken during non R.E.M. periods rarely if ever reported a dream.

Suddenly scientists had in their possession for the first time a behavioural index of dreaming and all sorts of puzzling questions could be answered. How long did dreams last? How many times in a night did one dream? Did everyone dream? What was the depth of sleep at which dreaming occurred? A series of experiments sorted out these problems and turned up a number of surprising facts, including that we spend up to 25 per cent of the sleep period in dreaming.

Further experiments in New York and California notably by William Dement were even more sensational. Subjects regularly deprived of the opportunity to dream by being woken at the onset of R.E.M. periods began to show psychological disturbance after a few nights, while a control group woken for the same number of times and for the same amount of time, but during non R.E.M. periods were relatively unaffected. In addition the dream deprived subjects, when finally allowed to sleep instead of dropping into a

coma like state of exhaustion spent significantly more of the sleep period than average in dreaming! Evidently we need to dream and perhaps the true function of sleep was to allow us to do so. But if this was true just what were dreams that they were so vitally important?

Computer Analogy

One possible explanation has been offered by a psychologist Dr Christopher Evans and a computer engineer Mr E. A. Newman both of the Division of Computer Science at the National Physical Laboratory. The first version of their theory *Dreaming—an analogy from computers* was published in the *New Scientist* in 1964.

To understand the idea behind the analogy it is necessary to know a little about some aspects of computer functioning. Computers are advanced calculating machines controlled by sets of programmes. These programmes are instructions to the computer telling it how to use its brain as it were, and they greatly extend the potential of the system. One programme for example might allow the rapid computation of say the average of a long string of numbers another might deal with the preparation of the salaries and wages of a big firm a third might control the distribution of goods from a warehouse. Technically speaking all the above tasks, and many more, could be handled with ease by a large computer and which task it was performing at any one moment would be decided by which programme had been selected.

Now computers are developing at a tremendous pace becoming more complex and powerful in terms of the range of operations they perform. Even at the present moment a certain amount of time has to be routinely set aside for an important series of operations involving the computers. These operations which are of particular significance to the theory involve the act of either clearing the system of old programmes or modifying and up dating them, and testing new programmes. In other words they ensure that the computer is equipped with the latest and most accurate sets of programmes to allow it to do its job properly.

Now it is an interesting fact that the clearing and up dating must be done when the computer is to use a technical term off line i.e. is uncoupled from any systems that the computer itself is controlling. To give an example if the computer handles the salary structure of a big firm then as income tax changes wages go up etc. the appropriate programmes have to be modified. If the computer is not off line when these modifications are made and the programmes run through then salaries and wages will be paid at some unsuitable time. Worse, if the computer were controlling the output from some chemical factory inaccurate or experimental programmes run on line could cause explosions and so on.

It is important to remember that to say a computer is off line does not mean that it is switched off—in fact it may be working like mad, but not coupled to the part of the exterior world it normally controls.

Now the brain is certainly a computer of a special kind, and must be controlled by sets of programmes—though these of course are not fed in by paper or magnetic tape. In addition it is more advanced than most electronic computers because it is *adaptive* i.e. it continually modifies its own behaviour and capabilities to meet the continually shifting conditions of the world around it. It is with computers such as the brain—and with the increasingly sophisticated man made devices of the future—that programmes revision and clearance processes will be quite vital. If the systems are to remain crisply efficient and more important are to make the correct responses to the changing environment.

In the Evans-Newman analogy sleep is the state in which the brain-computer is off line during which time the vast mass of existing programmes are sorted, out-dated ones revised in the light of recent experience, and useless ones or the remnants of modified ones cleared and eliminated. These processes take place for a substantial part of the night but because the brain is off line and consciousness suppressed

we are mostly not aware of them. However if for some reason our sleep is disturbed or when we wake in the morning as the conscious mind comes to it catches the programme operations at work and for a moment has no way of knowing whether the events are internal or external in origin. It sets to work therefore to try to make sense of the programme or fragments thereof that are being run through and the result is what we call a dream—though presumably we should call it an interrupted dream.

This approach not only helps to explain the importance of the dream process but also offers some answers to a number of interesting puzzles. For example a realisation that the logic of the brain's programming and storage system will follow its own internal rules and not necessarily correspond to the logic of the external world allows one to understand the Alice in Wonderland pattern of our dream life. Programmes which for instance deal with quite unexpected characteristics of the material stored in the brain—all events concerned with bicycles or spoked wheels might to take a completely *ad hoc* idea be the subject of a special programme and *ipso facto* a dream. Faced with such a weird assembly the conscious mind would struggle to impose a meaningful story on the experience and do the best it could with the material available.

Try checking this idea by examining the content of your next major dream. The trick, by the way, is to concentrate on the events within the dream and not be misled by the apparent fatuity of the story. Without too much effort the origin of these events will click into place—this was something from a magazine that from a conversation the other from some private train of thoughts of the previous day. Even the most outrageous absurdities will be revealed as muddled or highly coloured versions of recent experiences.

The computer programme analogy predicts that the amount of dreaming (and probably sleeping) is a function of the amount of new material (i.e. requiring changes in existing programmes) accumulated in the course of the day. Babies therefore for whom everything is new need to sleep and dream the most while old people, who tend to have inefficient information receivers and very static environments, would require far less.

Similarly there should be a rough equation between cerebral complexity in animals and their dream requirements, and thus follows pretty well. Chimpanzees require a fair bit of sleep though not as much as man while relatively simple minded creatures like sheep need a good deal less. Even further with insects, who have no complex adaptive computing systems in their brains sleep as we know it doesn't really occur.

The realisation that one of the main functions of sleep is to allow us to dream makes one think again about the role of drugs as hypnotic agents. Central nervous system depressants such as barbiturates or alcohol in large doses might well not only act as soporifics, but also push the sleeper down too deeply for him to dream properly—with unpleasant long term effects as a backlog of out dated programmes builds up. It is thus pushed too far the dream mechanism might well switch desperately into action when the brain was on line (awake) and the result would be hallucinations of an unpleasantly real kind—such as those which prevail in the delirium tremens of alcoholism.

On the other side of the coin is the suggestion that hallucinogenic drugs such as LSD might produce their spectacular effects by kicking the dream mechanism into action again when the computer is 'on line'. This would be contrary to the fundamental rules of cerebral mechanisms and while the inner world of the mind would indeed be revealed to the drug taker considerable risk would be involved.

Firstly one would predict a steady deterioration in his ability to distinguish between inner and outer reality—a condition reminiscent of the schizophrenic state. Secondly and no less horrifying is the possibility that on line dreaming would make one hyper-programmable—i.e. any stimulus fed in during this time would be incorporated into a major programme and thus trivial events would assume massive significance to the individual concerned. Incidentally this feeling of having had a revelation

out of trivia is commonly reported by LSD takers. The real risks it seems of LSD and similar drugs may not be in the arguable matter of chromosome damage but rather in its effects on one of the brain's most important functions—the dream.

PARKINSON'S DISEASE

Recent Advances

An outstanding advance in drug treatment of this disease has been made by the introduction of levodopa (L dopa) in 1970. The synthesis and eventual commercial production of this substance by the pharmaceutical industry notably by the Swiss firm Hoffmann La Roche has in itself been a major undertaking and something of a triumph for the research chemists. It is a matter of interesting historical fact that the compound was first isolated in the laboratories of Hoffmann La Roche as long ago as 1913. At that time the study of the biochemistry of the nervous system and brain was relatively new and the significance of the compound in terms of neuro physiology could not have been appreciated.

Parkinson's disease is a chronic disabling disease of the nervous system that is now in two out of three cases effectively controlled by levodopa. To understand and appreciate the results of research by physiologists, pathologists and biochemists into its causes it is necessary to understand something of the disease itself. It is no exaggeration to say that the use of levodopa has in many instances not only transformed the patient's way of life but that of his family or attendants on whom he has had so much to rely for his daily care.

The Disease

The disease is *paralysis agitans* or *Parkinson's disease*. The first name means literally 'shaking palsy' the eponym is the result of the first clearly documented description of the disease by James Parkinson a London surgeon in 1817. The disease is an ancient one. Mention of it can be found in 3rd cent. writings but the classical description of the disease and its course remains that of Dr Parkinson in his published monograph *An Essay on the Shaking Palsy* a copy of which can be seen in the British Museum.

The name 'shaking palsy' is apt for the cardinal symptoms are *tremor* with *muscle stiffness* which amounts to a *paralysis*. The onset is very gradual and the full blown picture of disease may take months or years to develop. The first symptoms may be a feeling of stiffness or weakness in one part of the body—a wrist joint or fingers. A fine rhythmic tremor of fingers or hands develops particularly noticeable while the limbs are at rest. Simple movements such as getting up from a sitting position become not only difficult to carry out but slow to start. The body is held in a rather statuesque manner with head bent forward, arms and hands held flexed and with a rhythmic tremor of fingers and thumbs characteristic of the movements used in rolling a home made cigarette.

The difficulty in moving virtually all the muscles leads to a characteristic type of shuffling gait. The feet barely leave the ground and with the centre of gravity very often over the toes as a result of the bent trunk and forward flexed head and shoulders the patient tends to totter forward under his own momentum and indeed may actually fall over. His appearance while shuffling thus is as if he were about to break into a little mincing run.

The features become characteristically expressionless unblinking and mask like with slight drooping at the corners of the mouth. The whole appearance is one of dejection misery and immobility. Furthermore, the knowledge that the disease is chronic disabling and incurable adds to the general feeling of despair and pessimism in any family unfortunate enough to have an afflicted member. Parkinson's disease affects some 50,000 men and women in Great Britain alone—about one in every thousand. It is a disease of later life, among the age group 50-70 and is twice as common in men as women.

Treatment

As with any disease of obscure nature and cause with an inevitably fatal outcome remedies of every kind have been applied by laymen and doctors alike over the many centuries that the disease has been with us. Parkinson in his essay mentioned above was understandably cautious until we are better informed respecting the nature of the disease the employment of internal medicine is scarcely warrantable but that did not stop the purgatives the arsenic or the blood letting favourite empirical remedies of his time.

The first notable advance in treatment was made by the French physician Charcot in the latter part of the 19th cent. He introduced *belladonna* which had some effect on the excessive salivation and muscle stiffness. Tincture of belladonna was virtually standard treatment by the beginning of the first world war and remained so right up to the 1950s. It was known that the belladonna alkaloids—*atropine* and *hyoscyne*—probably exerted their action on those parts of the central nervous system which seemed to be affected in some way by the disease and gradually synthetic compounds with similar actions replaced those older remedies. None of these substances did more than ameliorate symptoms—and not particularly effectively at that. None theless medicine could offer nothing better.

From post mortem and other studies it had gradually become clear that the seat of the mischief in this baffling disease was in a part of the brain an area concerned with the maintenance of many bodily activities of which we are never truly aware until something goes amiss. One of these activities concerns the tone of muscle, tone generally and the preservation of the right balance between muscles which have opposing actions. It is obviously necessary when bending the forearm for instance for the muscles whose action is to straighten the elbow to *relax* while flexor muscles do their work—or no movement would take place. And when the arm is at rest it is obviously necessary for any tendency for one set of muscles to overcome the other to be corrected—or the arm would not be still. All these co-ordinating activities are controlled below the level of consciousness in an area of the brain which contains the nerve cell computing centres—the *basal ganglia*. The particular area affected in Parkinson's disease is known as the *corpus striatum*. (The early neuro anatomists could only describe these different areas of the brain by their naked eye appearance only guessing at their probable function.) It is beyond the scope of this article to go further into the detailed pathological changes in those areas of the brain which have been described in subjects dying of the disease. It is sufficient to mention that until the later 1950s the changes described—essentially of loss of nerve cells and degeneration of axons which are the connecting fibres of such cells—were attributed solely to some type of senile degenerative process associated with age and possibly mediated by arterio sclerotic types of vascular degeneration in particular (such as atheroma see F30(1)). The incidence of the disease is greatest by far in the 50-70 year age group and that fact gave credence to such views.

However the general impetus given to medical research by the second world war led in particular to concentrated effort in the field of biochemistry particularly the biochemistry of transmitter substances or hormones. It had been known for a very long time that the opposing states of general bodily physiology—on the one hand the alert fight or flight state with blood flow diverted to muscles quickened heart beat raised blood pressure dilated pupils and general pallor and on the other the relaxed drowsy state of the contented post prandial dozer with slowed heart rate lowered blood pressure small pupils and flushed appearance—are basically controlled by the output of adrenalin and acetylcholine respectively. These two states—the sympathetic and parasympathetic—are mediated and maintained by the actions of the peripheral nervous system but are under the master control of the central nervous system—the brain and spinal cord.

The idea gained ground that the symptoms of Parkinson's disease—which are predominantly

those of parasympathetic or (acetyl)cholinergic activity—might be the result of an essentially chemical imbalance between two opposing substances in brain tissue itself. A discovery of major importance was made by three German scientists—Hornyiewicz and his colleagues—in 1961. These workers found that the adrenalin-like neuro transmitter compound *dopamine* was grossly lacking in the basal ganglia of patients with Parkinson's disease. Dopamine and acetylcholine have the same relationship in the central nervous system as adrenaline and acetylcholine have in the peripheral system. If dopamine concentrations fall then cholinergic activity predominates—and this is just what seems to be happening in this disease. Belladonna and its alkaloids exert their action by antagonising acetylcholine—and hence their use in patients with Parkinson's disease went some way towards restoring the balance and relieving the symptoms.

The anticholinergic drugs (now largely synthetic compounds with belladonna like actions) certainly gave some relief but the dose required to do so often meant that side effects—excessive drying of salivary and bronchial secretions—made life more uncomfortable for the sufferer than his untreated disease. Following on the discovery that dopamine levels in the brain were sub normal in the disease attempts were made to correct the situation by giving patients dopamine by mouth. Unfortunately dopamine while readily absorbed by the body does not get into the brain since the blood brain barrier is a physiological brain protecting mechanism that blocks the entry of many drugs and indeed some physiological substances as well.

Dopamine like many other chemical messenger substances in the body is normally produced on site as it were from an inactive precursor. This is *dihydroxyphenylalanine* or

DOPA which is derived from one of the amino acids those chemical units which form the complicated molecules of animal and vegetable protein. DOPA crosses the blood brain barrier readily—dopamine as has been pointed out does not. DOPA is readily converted to dopamine in the brain and in early experiments in man in 1962 a Canadian physician, Barbeau produced quite dramatic but short lived improvement in Parkinsonian patients by giving small doses of DOPA by mouth. The improvement was mainly in paralysis—the difficulty in *starting* and *maintaining* muscle movement—and was better than had up to then been obtained either with anti cholinergic drugs or with the highly specialised and sophisticated techniques in brain surgery which had been developed gradually since the early 1950s.

The early attempts to restore dopamine levels in the basal ganglia of the brain by oral DOPA were frustrated by the fact that if more than transient improvement were to be made much larger doses had to be given. Inevitably there were unpleasant side effects. At that time too DOPA was difficult and expensive to produce and mainly only available in what the chemists call the *racemic* form. Racemic compounds are mixtures of two chemically identical substances whose molecules differ in their spatial arrangements of atoms. One is, in effect, the *mirror image* of the other. Physical chemists are able to distinguish one form from the other by special techniques which enable them to look at molecules three dimensionally. In some examples polarised light can be used to distinguish one from its mirror pair by its ability to rotate the plane of polarised light to the left or to the right when it is passed through a solution. This is true of the D and L forms of DOPA. (Dextro and Laevo).

It was soon realised that the D form is not only virtually inactive as a dopamine precursor (it is a form not found naturally in the body) but is toxic. The L form, however seems to be the natural precursor, readily absorbed into brain tissue and much less likely to produce toxic reactions. Furthermore as equal parts of the D and L forms are present in the racemic mixture the same effects could be produced with half the dose of substance when the L form was used on its own.

Unfortunately the L form proved difficult to synthesise or separate from the racemic form

Supplies were scarce and costly in comparison to the DL form and the early trials, because dosage was kept on the low side were largely disappointing. The breakthrough came in 1967 when theoretical considerations led to the pioneering use of much larger doses than had been attempted heretofore by Cotzias and his colleagues in the U.S.A. They were forced to use DL DOPA, the L form being in extremely short supply and very costly but built up the dose given to their patients by slow carefully monitored steps to the maximum that could be tolerated. It was a case of titrating the patient to achieve maximum therapeutic effect with the minimum of unwanted side-effects. It was found to be the only way to get to a lasting effective dose without upsetting the patient in other ways. In some instances as much as 16 grams a day had to be given.

Nevertheless in spite of careful administration and the slow build up of dose levels there were many side effects which, if nothing else were disagreeable to the patient. Not only that but one patient's blood cell forming system was affected—a condition known as granulocytopenia—and this represents a potentially serious hazard.

By this time as a result of research effort within the pharmaceutical industry the effective and less toxic L form of DOPA became less expensive to produce and relatively less scarce than before. Cotzias and his co workers undertook a further trial in 1969 using L dopa alone. Again maximum effect was achieved by working up to an optimal dosage, in that trial there were no serious or potentially serious side-effects and the solely troublesome ones—nausea vomiting abdominal pain and the like—were found to be dose dependent. In other words they could be avoided by reducing the quantity of L dopa used. 28 patients were treated in this trial—and all improved 20 of them markedly or dramatically.

It will be recalled that the dominant and most distressing features of the disease are the stiffness the slowness the difficulty in initiating movements and the tremor. The first three are known to the physician as rigidity bradykinesia and akinesia and it is on these that levodopa has its maximum therapeutic effect. Tremor may respond after prolonged treatment in some patients but not all. The effect on the patient when he finds he can get up from his chair or his bed *unaided* when he begins to *walk* instead of shuffle when he can cough healthily to clear his throat when his handkerchief can be kept in his breast pocket instead of being held constantly to drooping mouth when he can feed like others and feel his face break into a smile is dramatic. And if he has been somewhat dysphonic (having difficulty in speaking through stiffness of jaw and tongue muscles) as many patients are the return of normal or near normal speech is perhaps the final booster to a morale that has often sunk to its lowest level. His renewed optimism spreads to family and friends. Return to work becomes a reality and restoration of independence naturally follows.

It must be mentioned that some patients fail to respond at all perhaps something less than one in three. There is as yet no means of predicting response to levodopa. But it should not be forgotten that although levodopa now tops the list of symptomatic remedies for Parkinson's disease the others remain—the anticholinergics amantadine and mentioned briefly above stereotaxic surgery. And most patients can expect some response to one or other of these.

Since 1969 there have been many further clinical studies and it has become abundantly clear that in levodopa physicians have a drug which is as important a step forward in the treatment of Parkinson's disease as the introduction of insulin was in the treatment of diabetes. But it must be remembered that like diabetes Parkinson's disease is only symptomatically improved. Its true nature is still not understood and the precise mode of action of levodopa still unknown. The effects of its long term administration cannot be assessed as yet. And whether this treatment, dramatic though it is in many cases, will have any effect on the natural history of Parkinson's disease is very much an open question.

PART IV INDEX AND GLOSSARY

- Abortion** The termination of pregnancy from whatever cause before the child is capable of independent existence.
- Abortus febrilis** An infectious disease known as undulant fever 15 (1)
- Abrasion** Any injury which rubs off the surface skin
- Acidity** See under *Pephic ulcer* 36 (1)
- Acne** 53 (2)
- Acromegaly** A state of excessive growth of the body caused by overaction of the pituitary gland in the base of the brain 43 (2)
- Actinomycosis** 15 (2)
- Acute chorea** or St Vitus' dance 49 (1)
- Acute nephritis** 45 (1)
- Addiction to drugs** See *Drug abuse* 22
- Addison's disease** 43 (2)
- Adenoids**, 32 (1)
- Adrenal cortex**, 43 (2)
- Adrenal medulla**, 43 (2)
- Adrenocorticotrophic hormone (ACTH)** 43 (2)
- Air we breathe** 4 (1)
- Agranulocytosis** 26 (1)
- Alcoholics Anonymous** 6 (2)
- Allergy** Abnormal sensitivity to any substance which does not affect normal people
- Alopecia** 52 (2)
- Amenorrhoea**, 56 (2)
- Amnesia**, 47 (1)
- Amoebae** 8 (1)
- Amoebic dysentery** 17 (2)
- Amphetamine** 23 (2)
- Amphotrophic lateral sclerosis** 48 (2)
- Anæmias** 24-25.
- Anæsthetic** Any drug used by surgeons to remove pain during an operation.
- Anencephaly** 48 (2)
- Aneurism**, 30 (2)
- Angina pectoris** 28 (2)
- Ankylosis** Partial or complete fixation of a joint as after some types of arthritis. In other cases deliberately produced by surgery
- Ankylostomiasis** 16 (2)
- Anorexia** Loss of appetite
- Anterior pituitary** 43
- Anthrax** 15 (1) 9 (1) 4 (2)
- Antibiotics** are drugs which act directly against the organism causing the illness by interfering with its growth or some other aspect of its living mechanisms. Of all drugs which are used against bacteria antibiotics do least harm to the patient's own tissues some do have unwanted side effect but many have none at all See 4 9 22
- Antihistamine drugs** 4 (2) 5 (1)
- Antiseptics**, 8 (2)
- Anxiety neurosis** 51 (2)
- Aortic diseases**, 30 (2)
- Aphasia**, 47 (1)
- Aplastic anæmia**, 25 (1)
- Appendicitis** 37 (1)
- Arteriography**, 43 (1)
- Arthritis**, 54 (2).
- Artificial respiration** (kiss of life) 21 (1)
- Ascites** 39 (1)
- Asphyxia**, 20 (2)
- Aspirin and "upset stomach"** 5 (1) 25 (1) 36 (2) see also *Headache*.
- Asthma**, 32 (1)
- Atheroma** or *Atherosclerosis* 30 (1)
- Athlete's foot**, 8 (1) 15 (2).
- Backache** A symptom which may be caused by many different diseases—sometimes disease of the vertebrae themselves sometimes strain of the ligaments and sometimes inflammation or spasm of the surrounding muscles. Lumbar is usually due to inflammation of the muscles in the small of the back. Backache from purely local causes may be treated temporarily by applying heat in the form of a liniment poultice or a rubber hot water bottle and taking two aspirin tablets a day. On the other hand many cases of backache are due to disease elsewhere. The most important thing is to find out the cause and therefore a doctor should be consulted.
- Bacteria**, 7 (1) **Bacterial diseases** 12-15
- Bacteriophage** 7 (2)
- Baldness** 52 (2)
- Barber's rash**, 53 (2)
- Barbiturates** 23 (2)
- Bell's palsy** 50 (2)
- Benzedrine** The proprietary name of a drug known as amphetamine See 23 (2)
- Beri-beri**, 42 (2)
- Berry aneurysm** 49 (2)
- Bilharzia**, 18 (2) 16 (1)
- Birth control**, 56
- Blackwater fever** 17 (2)
- Bladder** See under *Urinary diseases* 44 (2)
- Bleeding diseases**, 26 (1)
- Blepharitis**, 55 (1)
- Blood, function of the** 24
- Blood, diseases of the** 24
- Blood Groups** Human blood plasma contains factors which clump or agglutinate the red cells of some other people's blood. The main blood groups are called A, B, AB and O. The plasma of group A blood contains an anti B factor and *vice versa* so that people of groups A and B cannot accept each other's blood. Group AB contains neither anti A nor anti B factor and people with this group can therefore receive transfusions from both but can give to neither. Group O contains both anti A and anti B and can therefore receive blood only from group O but can donate blood to all groups. It is important that transfused cells should not be agglutinated by the factors in the recipient's plasma. Apart from the so called ABO system there are several other blood groupings one of which is mentioned under *Rhesus Factor*
- Blood poisoning (septicæmia)** 14 (2)
- Blood-pressure** 29
- Blood-vessels diseases of the** 30
- Blue babies**, 5 (2)
- Botulism** 14 (1)
- Brain** See under *Nervous system* 46 **Physical injuries** 19
- Brain tumour** 50 (1)
- Breasts**, 55 (2)
- Bronchial asthma** 32 (1)
- Bronchiectasis** 32 (1)
- Bronchitis** 31 (2)
- Bruises and abrasions** 19 (2)
- Bürger's disease**, 31 (1)
- Burns and scalds** 21 (2)
- Cachexia** Extreme wasting due to disease
- Cæsarean operation.** When the abdomen has to be opened to remove the child, named after Julius Cæsar who is said to have been born in this way.
- Caisson disease** 31 (1)

- Cancer of the breast 55 (2)
 Cancer of the cervix 56 (1)
 Cancer of the colon 37 (2)
 Cancer of the lung 33 (2) 34 (1)
 Cancer of the oesophagus 36 (1)
 Cancer of the rectum 37 (2)
 Cancer of the stomach, 37 (1)
 Cancer test (cervical smear) 56 (1)
 Carbohydrates The scientific name for sugars
 starches and cellulose 34 (2) 40
 Carbon monoxide poisoning 21 (1)
 Carbuncle A large boil
 Cardiac neurosis 27 (1)
 Cataract, 56 (1)
 Cerebral abscess, 49 (2)
 Cerebral embolism 49 (1)

 Chadwick Sir Edwin (1800-90) English social
 reformer 6
 Chancroid 16 (1)
 Change of life 44 (1)
 Chickenpox 10 (1)
 Chilblains 53 (1)
 Chill This is not a proper medical word but
 refers to the symptoms that occur when one
 first becomes infected with any germs which
 cause fever. When such germs enter the body
 all the defending processes are mobilised and
 speeded up. The white cells in the blood in-
 crease in number and the amount of energy
 used is greater than normal, causing the tem-
 perature to rise. This rise in temperature
 increases the ability of the body to fight back
 and in order to retain heat within the body the
 blood vessels in the skin contract so that less
 heat is lost by radiation. This makes the skin
 cold and pale. What is ordinarily called a chill
 is merely an infection by the germs causing cold
 and influenza. But a chill may be the pre-
 liminary to almost any infectious disease such
 as measles, mumps, scarlet fever, pneumonia
 and so on. The best treatment when the tem-
 perature is raised is to go to bed with as much
 warmth as possible. Hot drinks and hot water
 bottles are helpful. *See* Colds 10 (2)

 Psychosomatic diseases Psychosomatic diseases are those physical ailments due to emotional causes. They include such complaints as high blood pressure gastric ulcer certain skin diseases and certain glandular diseases (*e.g.* exophthalmic goitre). Most physicians nowadays believe that all diseases may show a greater or less degree of emotional causation that physical and mental factors are both present in all illness. Even in psychosomatic illnesses heredity and other factors play a large part. Briefly the main cause of these diseases is worry. The importance of this lies in the fact that they cannot be cured without dealing with the fundamental cause. *See also* New Views on Medicine 3 (2)

 Rhesus Factor Apart from the ABO blood group system (*see* Blood Groups) there is another blood group system (designated the Rh system or Rhesus system). Everybody is either Rh positive or Rh negative. Three positive factors (denoted C D E) and three negative factors (denoted c d e) are involved. This system of blood factors is inherited separately from the ABO group so that one may be A Rh+ or A Rh- etc. Both the

- positive and the negative factors are antigenic and if introduced into other blood they will stimulate the production of substances which act in some way against the cells introduced. We inherit some factors from each parent and it may occur that a Rh+ baby is born of a Rh- mother. In this case some of the baby's blood may and often does obtain access to the mother's circulation and stimulate her to form substances harmful to the baby's red corpuscles. If these leak back to the baby through the placenta some of the baby's red corpuscles may be adversely affected. This does not usually occur with the first baby but may become increasingly serious with following pregnancies.

- Rods and Cones** are cells in the retina of the eye which convert light into nervous impulses which can be interpreted by the brain. In man the cones are associated with colour vision and used during daylight. The rods are concerned with twilight vision and do not give rise to the sensation of colour. It is probable that there are three types of cones responding to red, green and violet other colours being a combination of these three. Rods contain a pigment visual purple which is sensitive to light. Vitamin A is necessary for the production of this substance. The changes produced by light on the visual purple initiate a nerve impulse but the exact mechanism is unknown.

AN INTRODUCTION TO PSYCHOLOGY

This section is concerned with the science and study of the human mind, a territory rich in mystery, a glimpse of which we catch through the enigma of memory, and in the misty drama of our dreams. It represents a unique guide to one of the most exciting experimental sciences of today.

TABLE OF CONTENTS

I. Introduction – discusses the role of the psychologist and his principal fields of study – the brain and human behaviour.	3-7
II. Perception – includes the study of the way information is gathered by the brain and how it is interpreted.	7-16
II. Learning and Memory – deals with the way the information is stored once it has been gathered, and how it is retrieved when wanted.	16-23
IV. Motivation – studies the vital question of why a human or animal interacts with its environment and does one thing rather than another.	23-27
V. Personality and Thinking – tackles the abstruse problems concerned with consciousness, self-awareness, intelligence, thought and language.	27-30

AN INTRODUCTION TO PSYCHOLOGY

The purpose of this section is to provide a general introduction to the young but expanding science of psychology. The topic itself is of course enormously broad and can only be summarised at best. However, it is hoped it will serve to give some idea of the fascinating material that psychologists study and also of their occasionally remarkable and always interesting findings. The section also aims to dispel some of the illusions that have surrounded the subject and to define its boundaries to the extent that the reader will not only begin to understand what psychology is but also what it isn't!

I INTRODUCTION

What is a Psychologist?

The popular image of a psychologist is a fairly well defined one—he is a man who treats mental illnesses in the way that a doctor treats physical ones. His principal equipment apart from a well furnished consulting room is a leather couch for patients to lie on, a well stocked library and a cabinet of mysterious drugs of one kind or another to send them off to sleep. He is particularly interested in the dreams of his clients and may use some form of hypnosis to study their repressed thoughts and secret emotions. He is probably very wealthy because of the enormous fees he charges and may speak with a central European accent.

Silly though the above description may sound, it is nevertheless unfortunately true that it corresponds pretty closely to the kind of picture that most people have of a psychologist and of the kind of work he does. Remote though this description is from the truth—at least as far as the vast majority of psychologists is concerned—the average person can be forgiven for having it firmly lodged in his mind for in literally hundreds of movies, TV and radio plays, books and novels this is the picture that has been painted. One of the first tasks of this section will be to attempt to straighten out some of these misconceptions so that a clearer idea of the nature of psychology can be given. While the mysterious and unfortunately rather glamorous aspect of psychology that concerns itself with mental illness and its treatment is certainly one facet of the topic, there is a good deal more to it than that. Further, more the part of psychology which deals not with the abnormal but with the strictly *normal* brain is the area which has best repaid scientific study and as we hope to show, which has uncovered the most exciting raw material.

This section therefore begins with a clarification of the role of the psychologist and follows with a brief introduction to his principal fields of study—the brain and human behaviour. After this we take in turn the four main areas of study which assist him in his quest for an understanding of human nature. These are Perception, Learning and Memory, Motivation, and finally Personality and Thinking.

One of the main sources of confusion in people's minds arises from puzzlement over the distinction between four commonly used words which, while differing in meaning in important respects, are almost invariably lumped together as one. These are (1) Psychiatry, (2) Psychoanalysis, (3) Psychotherapy and (4) Psychology. The words do look and sound rather similar but it is not difficult, once the right definitions have been given, to sort the four clearly out in one's mind. Let's take psychiatry first.

(1) **Psychiatry** is the art of *treating* mental diseases or illnesses by medical means and it is a specialist branch of medicine entered through the medical profession and taught at hospitals or universities. A psychiatrist therefore is quite invariably a doctor of medicine with ordinary medical degrees but with a postgraduate training in mental illness and its treatment. No one may call himself a psychiatrist unless so qualified, and

no one may prescribe drugs or surgery in treating mentally sick individuals unless he is medically qualified. There is an important point of issue here for in England and many other countries people not trained as psychiatrists may nevertheless diagnose and treat mental illnesses—provided that they do not use drugs or surgery to do so.

(2) **Psychoanalysis** is a particular form of examination or diagnosis of an individual's mental state based on the theories of the mind and personality advanced by Sigmund Freud and his colleagues or followers and the reader may like to turn to the entry on J42. An interesting feature of psychoanalysis is that unlike psychiatry it may be practised without medical or academic qualifications on the part of the analyst. A special training analysis at a recognised institute is normally undertaken by the would-be practitioner, however this is not normally made available to individuals unqualified in medicine or psychology.

(3) **Psychotherapy** is the practice of treating mental diseases or illnesses by more or less any means. Thus strictly speaking both the psychiatrist and the psychoanalyst are psychotherapists—as are any other individuals using reputable methods who offer therapy for the mind. Once again notice that this implies that one may call oneself a psychotherapist irrespective of whether one has medical or academic qualifications, and it is a word that tends to be adopted with impunity by a good many quacks and charlatans who can of course do fearful damage in this tricky area.

(4) **Psychology** is literally the study of the mind (or soul) but its area has broadened somewhat in the last century as we have learned that one cannot consider the mind as totally isolated from the body and it now includes the study of human personality and behaviour. Psychologists also study the behaviour and brain of animals where ever such studies throw light on human behaviour. It is important to realise that psychologists are first and foremost trained as scientists rather than as medical experts and do not necessarily take much interest in abnormalities of the brain and mental processes. Those who do tend to take postgraduate training in what is known as clinical psychology and may add to their knowledge by undergoing training in psychoanalysis.

It is obvious that there is a good deal of overlap between these four aspects of the topic and in the following section we shall be entering the territory of psychiatry and psychoanalysis to some extent but mainly concerning ourselves with psychology—the science and study of the human mind, personality and behaviour.

1 The Brain

From the moment of our birth and emergence from the security of the womb our body is controlled and dominated by a single but complex organ, a library switchboard signal box com-

puter and many other things all rolled into one—the brain (see F37(2) P46). Very properly encased in a hard shell of bone and equipped with instruments for detecting food or danger at a distance—eyes, ears, etc.—the brain matures slowly unlike other bodily organs reaching its peak of efficiency and potential approximately 18 years after birth. From then onwards slowly and almost immeasurably at first but with remorseless steadiness it slides into decline. Its proper functioning determines the normality of the behaviour of the individual and the part he can play in society; its efficiency determines to some extent his intelligence and his ability to compete; its storage capacity and information retrieval system his potential to learn and remember. In addition its computing power determines his creativity and is the primary function which distinguishes between the mature human being and the other animals on earth. No organ or complex of organs is guarded and shielded so carefully.

The brain is the main focus of interest for the psychologist for there can be little doubt that the key to the understanding of human personality and behaviour lies locked up within it. Its complexity of course is daunting but thanks to physiological and anatomical studies it is possible to get at least a general idea of what's going on. In the first place the brain acts as the principal co-ordinator of messages coming in from the various sense organs and then as the dispatch point for the appropriate responses. This co-ordinating centre is easily best developed in man and is present in most of the higher animals. Simpler creatures however such as amoebae and certain tiny worms get along without any important co-ordinator of nervous impulses and respond diffusely to changes in the environment—moving vaguely away from things that annoy or damage them and towards food or other pleasant things. Such animals are literally the slaves of their environment incapable of setting up goals to achieve and with no facility for computing the consequences of any action. One important branch of the evolutionary tree shows a steady trend towards increasing brain size and with it freedom from this slavery.

In the second place the brain acts as the storehouse of information which the senses have gathered at some time in the individual's life. To us it may seem obvious that we have a memory—a place for looking at things that took place in the past—and indeed it is hard to imagine ourselves without one. However a large number of creatures get by with only the most limited of memory systems and some with none at all. Clearly a good deal must depend upon how long an animal is to live. If its life span is to be brief then it need not set aside much room to store information from its past. If it is to live for many years, survive in a changing and generally rather dangerous environment and learn by its mistakes and its previous achievements then this ability to refer back to the past is obviously essential. In human beings mechanisms of learning and memory are of vital importance and we will devote a good deal of this section to discussing the way in which psychologists study these.

The third primary function of the brain is to provide the computing and decision making processes which dictate so much of human and higher animal behaviour. It is also in the case of man the centre of consciousness and at the same time that elusive faculty we call personality.

2 How Does the Brain Divide up its Functions?

Nowadays we rather take for granted that important things such as thinking, remembering, etc., are mediated through the brain and it comes as something of a shock to recall that early philosophers located the majority of such processes in the heart or the stomach! Even today a good deal of controversy exists over exactly which part of the brain does what and as we shall see when we discuss the contradictory experimental evidence later there is even a suggestion that certain processes are dealt with by the brain as a whole rather than by some specific part. However the picture is reasonably clear.

In the first place the brain is composed of a

vast number of cells—the building blocks of all living systems—which in this case have become highly specialised and stretched out rather like telephone lines. These are known as nerve or neural cells or yet again as neurones. They act as communication units receiving electrical signals from other parts of the body. Comparative anatomists are able to trace the routes of whole chains of cells starting at say the finger tips and finishing up in a particular slab of the brain where such tactile messages are gathered and interpreted. On the whole messages from the eyes tend to finish up in the back of the brain or occipital lobes; messages from the ears nose etc. on the side or temporal lobes. In the front exists a large chunk of nervous tissue with a rather mysterious function inasmuch as it seems to be more directly related to the personality and mood of its owner than to any of his senses. In addition there are parts of the brain concerned more with output than input—the so called motor areas which dispatch the signals commanding various parts of the body to move. Finally there are the parts principally involved in the storage of information memory etc.

All these areas we have been talking about up till now are known as the cerebral cortex and they are located on the outer surface of the brain itself—set right up against the inside of the skull. You should by now have gathered that the cortex deals largely with psychological factors closely tied up with consciousness and awareness—seeing, hearing, thinking, remembering, etc. This ties in rather nicely with its alternative name the neo cortex (or new tissue) for in evolutionary terms this part of the brain is new. In general the closer that an animal species approximates to man the greater the proportion of its brain is assigned to neocortex and the more the particular animal is capable of independent deliberate and purposeful activity.

Tucked in beneath the cerebral cortex growing out of the spinal cord are the so called lower centres—the old brain. Here in a number of specialised blocks are located the control centres which deal with the most automatic (but no less important) bodily functions such as cardiac activity, respiration, temperature, etc. and which it is unnecessary or inconvenient to keep under conscious control. Damage or injury to these centres is generally very serious whereas damage to the outer layers of the brain, even when extensive, can have surprisingly little effect on the individual's way of life.

To sum up we note that the brain is divided into two major functional areas in evolutionary terms—the old and the new. The former largely deals with the vital automatic processes and the latter with the receiving and interpreting of sensory input and the decision making processes which guide our interaction with the outside world. Clearly this is an enormously simplified picture (specific aspects of this topic are dealt with in greater detail later) and the brain and central nervous system (CNS) is complicated almost beyond description with much of its mechanics and rules of operation still poorly understood. How then can one set out to study it properly and unravel its secrets?

3 Methods of Studying the Brain

Psychologists and physiologists favour many approaches to finding out how the brain works and while it won't be possible to look at them all in this section it will be worthwhile spending a bit of time on some of the most important lines of attack. These can be classed under the headings (1) comparative anatomy, (2) surgical tissue destruction, (3) electroencephalography, (4) microelectrode recording, (5) biochemical analysis, (6) behavioural research and (7) introspection. Some of these are really only possible with animals as the experimental subjects and others are more suited for research on human beings.

(1) Comparative Anatomy

This is perhaps the most obvious and logical method of all but it has one serious and insurmountable drawback. Suppose that one wanted

to find out how a motor car engine worked and that one had no prior knowledge of its operation but knew what one looked like from the outside. Finding instruction booklets or advice from motor mechanics the best method might seem to be to get hold of a complete engine and take it apart to examine its components. Given enough skill one might even be able to put it back together again. The chances are that with a relatively simple device such as an automobile engine an intelligent person would begin to see the principles of operation. However until he had actually watched it at work and studied the effect of say depressing the accelerator or pulling out the choke his comprehension of the device might be limited and he could well come to some funny conclusions about its function and operating habits. This approach is essentially that of the comparative anatomist who sets out to study the brain by examining a dead specimen peering at it through a microscope cutting out bits here and there and hoping to work out what each section contributes to the whole. Unfortunately whereas the average motor car engine probably contains a maximum of about 1 000 discrete and separate components some of which are rather large and obvious the brain contains a conservative minimum of about a thousand million neurones or nerve cells and no large and obvious moving parts to give the anatomist useful clues. It is little wonder therefore that while students of the brain adopting post mortem dissection have in the course of the last few centuries acquired a pretty clear picture of the way in which the brain is laid out—an anatomical atlas so to speak—most of the principles of cerebral operation are still more or less unknown. One of the great drawbacks of this system as you will probably have guessed is the fact that anatomical dissection and analysis can only be done in the dead animal.

(2) Surgical Tissue Destruction

To return to our rather inexact analogy with the motor car engine let us assume that our investigator finds himself with a working running engine to play with. Let us also assume that he has already made himself pretty familiar with the anatomy of the dead engine and has perhaps formed some hypotheses as to what certain parts of it do. For example he might have a suspicion that the carburettor and the sparking plugs were particularly important or that a key to the complete device working was that the pistons should move up and down in the cylinders. One of the first things he might do would be to systematically remove what he considered to be important parts of the engine and note how its performance was effected. Using this technique of selective removal he might soon begin to confirm or reject his hunches and a gradual comprehension of the function and capabilities of the engine would build up in his mind. He might find that whereas the removal of one sparking plug did not stop the engine it would lower its pulling power. Removal of the carburettor in toto would be calamitous while twiddling with it might have unpredictable effects making it run better or worse. On the other hand, filing bits off the iron cylinder block would make no difference whatsoever. Once again the psychophysicist is faced with something immensely more complex when he studies the brain but there is nevertheless obviously something to be gained by adopting a similar procedure with the working or living system. The systematic removal or destruction of parts of cerebral tissue has in fact been one of the most rewarding approaches adopted by brain scientists, though there are naturally severe limitations to the technique. In the first place such surgery cannot be performed on human beings except where it is a necessary feature of therapeutic brain surgery (e.g. as when removing a brain tumour) and can only be justified in living animals in the interest of serious and clearly defined scientific research. (Despite the assumptions of anti vivisectionists no reputable scientist enjoys performing experimental surgery on living animals and these are always conducted in such a way as to cause the creature as little distress and suffering as possible.) In the second place the very act of surgery itself probably introduces

side-effects which serve to complicate the picture. However this technique when skillfully used has led to some informative experiments.

(3) Electroencephalography

As we have said earlier the principal building blocks of the brain are the neurones specialised cells devoted to the transmission of information from one part of the body to the other. This transmission is effected by a change in the electrical potential of the cell along its long stem. The main bodies of cells tend to be pressed up against one another and when a change in potential occurs in one this tends to trigger off a similar response in a neighbouring cell at a junction point known as a *synapse*. Incidentally the long stems of the cells (which may be a yard or more in length in certain parts of the body) are covered by an insulating sheath which prevents the electrical message leaking out en route and which makes them strangely similar to the kind of electrical wires and cables we use in telecommunications. With a thousand million cells jammed up together in the head all of them propagating electrical signals in one way or another it should not surprise anyone to learn that sensitive recording devices can be used to get a picture of the overall electrical activity going on in the brain. Studies of this type (electroencephalography or EEG for short) couldn't begin until suitable recording machines had been developed and thus although scientists had been pretty confident that the brain was a potent source of electrical energy since the middle of the 19th cent. it wasn't until the 1920s that anyone was able to get a readable picture of this. The pioneers in this technique were the physiologists Berger and Adrian, who attached little electrodes to the outside of the human scalp and by hooking these up to amplifiers and then to special recording pens were able to get a kind of plot of the electrical activity going on within. To their surprise what emerged was not just a meaningless hodge-podge of electrical noise but rather a series of precise and elegant rhythms the frequency and amplitude of these depending upon the part of the brain where the electrodes were applied, and also—most excitingly—on the individual's mental state at the time of the recording. As time has passed and recording technology has advanced an immense amount of data has been gathered on these so-called brain waves and while it is true to say that the high hopes of the pioneers who believed that they were about to unravel the brain's mysteries almost overnight with this technique have not been realised the EEG has proved its worth in more ways than one. In medicine for example certain disruptions of the normal brain wave pattern can give clear indications to the expert of the presence of epilepsy or determine the site of otherwise totally inaccessible brain tumours. The EEG can also be enormously useful in evaluating the effectiveness and mode of operation of new drugs and is helping in our understanding of the nature of sleep—the EEG of a sleeping person differs significantly from that of a waking one. Curiously one of the most promising looking of the many rhythms which the brain emits—and one of the first discovered by the English scientist Adrian the so-called alpha rhythm, has turned out to be one of the most disappointing. The alpha rhythm which is generally picked up by electrodes attached to the back of the head (over the occipital or visual cortex) is a beautifully neat and stable wave of about 14 cycles per second frequency. It is present when the individual is relaxed and has his eyes closed. Opening the eyes and looking around, or alternatively keeping them closed and doing a bit of mental arithmetic, causes the rhythm to disappear and the hypothesis was soon advanced that alpha was a reliable index of the rather abstract mental state known as "attention." Unfortunately for this convenient idea on further study it was found that the rhythm did not always behave as it should sometimes doing exactly the opposite to what was expected of it. Furthermore some measurable percentage of humanity—about one in ten of otherwise normal individuals—show no alpha rhythm at all, which has led critics of electroencephalography as a technique to ask

sarcastically whether such people were incapable of deciding whether to attend to something or not'. All these drawbacks aside the EEG is still one of the best ways of getting some kind of index as to what is going on inside the head of a human or animal without resorting to surgery or interfering seriously with normal thought processes.

(4) Microelectrode Recording

For all practical purposes the record obtained by the EEG is a gross overall view of the brain at work. The waves and rhythms encountered must at the least represent the sum of the activity of literally hundreds of thousands of neural cells presumably firing more or less in synchrony. Going back once more to the motor car analogy the EEG could be likened to a garage mechanic listening with a stethoscope to the pulsing of an engine when running at high speed. Changes of speed adjustments in carburation or timing etc would give characteristically different running sounds but little if anything could be deduced about the state of activity of an individual component unless it were a very large one. Much the same limitations only on a gigantic scale surround the use of the EEG as a device for measuring specific aspects of brain activity. Quite recently however an interesting technological development has occurred which allows a more precise and delicate analysis of cortical cell firing to be undertaken—in fact to allow even the output from a single neural cell to be monitored. This technique involves the use of what are known as microelectrodes: tiny shivers of metal thousands of an inch in diameter which when in contact with an electrical source—in this instance the body of a nerve cell or neurone—transmit a pulse of electricity to an amplifier and recording apparatus. Microelectrode recording involves inserting electrodes of this kind in selected areas of the brain of an animal and by means of a precision adjustment positioning the electrode so that it is touching up against the body of a single cell. We shall discuss the remarkable findings which have come from experiments of this kind later in the section on Perception. Microelectrode techniques incidentally can on occasions be used with human subjects. In such cases naturally the opportunity arises when an individual is undergoing brain surgery for say the removal of a cerebral tumour. In these circumstances with the patient's permission the surgeon may perform experiments to study single cell responses with results which have been of great interest.

(5) Biochemical Analysis

The fifth major approach to the study of the brain to consider is that of biochemical analysis. For various reasons there has been a growth of interest in the microstructure of cerebral tissue not just the neural cell but in its basic constituents—in other words at the molecular level. Clearly there is not much hope or point in trying to record the behaviour of molecules by electrode recording or even by microscopic visual analysis so some other method must be found if one is concerned with this level of analysis at all. This is where the psychologist teams with the biochemist—an example of the kind of interdisciplinary approach which is becoming common in brain research. As with much of the chemical analysis performed in other fields scientists discover the nature of the substance they are examining by observing its behaviour when mixed with other chemicals or compounds. Crudely speaking one mixes the unknown substance with some known chemical and simply watches what happens: the reaction which follows giving clues as to the nature of the chemical under study. Now in the case of the brain or the constituents of neurones it is obvious that one is dealing with more than one single substance so the first problem is how to separate the constituents in order to study them individually. To achieve this biochemists use a number of techniques such as chemical separation, simple heating and even whirling the material round at great speeds in centrifuges. The biochemical approach to brain research is a bit too complicated to deal with in

detail here but in the view of many it is one of the most promising avenues open to scientists in this field.

(6) Behavioural Research

Psychologists are interested not merely in the structure of the brain of humans and animals but also of course in their behaviour. By behaviour one means the way in which the individual interacts with its environment and its reasons for doing so. A study of what when and how a creature does something can tell one a good deal about the rules that govern behaviour. The way in which a bird builds its nest, a cat rears its kittens, a dog threatens another dog frequently follow set patterns and presumably have something to do with the way in which at least a part of its brain is organised. Careful study of such behavioural patterns even allows one to make certain predictions about what an animal will do next in a given set of circumstances—and once one is able to predict accurately one has generally discovered something important. Studying animals (or people) in the wild is easier said than done and tends to be frustrating because of their tendency to do unpredictable things and their general disinclination to perform to order. Furthermore the range of behaviour that one can study by such methods is limited to the so-called instinctive actions which are frequently simple in function and execution. The alternative is to confine the animal in a laboratory and observe its reactions to an experimentally controlled environment. In this way one can study its learning and memory processes, its sensory mechanisms, its intelligence and capacity to reason, its behaviour under conditions of stress, its preference for various foods etc. etc. Behavioural research of this kind has turned out to be almost the most important method employed by psychologists in their attempt to understand the brain and while it has its inevitable limitations we will be examining the contribution it has made in more detail under various sub-headings.

(7) Introspection

The oldest and perhaps most obvious method of studying the brain was surely to think about it! This was the method adopted by early philosophers who believed that if one was sufficiently logical and intelligent one could work out the solution to practically anything. Unfortunately while the brain, mind etc might seem to be an ideal subject for its own thought processes this method of analysis—known as introspection—just doesn't seem to work in the way that it should. The principal problem is that much of the brain's activities are exceedingly rapid and automatic as anyone can demonstrate for them selves. For example turn your head and look at an object on the wall. It will be perceived and recognised apparently instantaneously. Even if you can detect a faint lag between the act of inspection and the act of perception it is quite impossible to describe the steps or stages in the process. Much the same applies to other important mental faculties. One cannot merely by thinking about it say how one actually learns something or how one calls an item up from memory. It was realising the relative hopelessness of this quest which led philosophers interested in the brain to convert themselves in the middle part of the 19th cent. into psychologists and adopt an experimental rather than an intellectual approach to the problem. However it should be equally clear (though many psychologists seem to have forgotten this) that there is a whole world of material which does not seem to make itself available to any of the experimental approaches (1-6) which we have described above. The study of language itself is a good example being part of our mental life and thus of great interest. Similarly certain features of abnormal psychology ranging from the bizarre thought processes of schizophrenics to the near mystical states of mind reported by artists and poets or the distortions of perception and personality induced by the hallucinogenic drugs are central to the topic of psychology and are clearly only approached in the first

instance through some measure of introspection. What too of the raw material of psychoanalysis and the rich glimpses of the interior of our minds granted us through our dreams? These are merely a few examples to highlight a single point that—when studying the brain we should not ignore the mind a power to look in on itself.

This concludes our condensed survey of some of the principal methods used by psychologists and their colleagues in attempting to get to grips with their exciting and challenging field. The reader may have been surprised by a number of things one of which must surely be how very much wider is the territory covered by psychology than is commonly believed.

4 What do Psychologists Study?

We now come to examine the main areas making up the subject matter of psychology. There are all kinds of ways of breaking this material down and as the topic is so immense (and enlarging quite rapidly) one or two important aspects will have to be left aside. We shall only refer in passing for example to the important sub sections of Child Psychology, Industrial Psychology and Ergonomics for these need to be treated separately if they are to be properly understood. Furthermore much of the material inherent in Sociology will have to be passed over for similar reasons. The reader will also notice some overlap between the various headings which merely confirms what one ought to suspect—that in studying human beings or living animals it is really impossible to segment the approach completely. A person is an entity and something more than the sum of his various parts.

For the purposes of this Introduction we will consider Psychology as constituting principally the study of four major factors—

(1) Perception which includes the study of the way information is gathered by the brain and how it is interpreted

(2) Learning and Memory which deals with the way the information is stored once it has been gathered and subsequently how it is retrieved when wanted

(3) Motivation which includes the vital topic of why a human or animal interacts with its environment and why it does one thing rather than another and

(4) Personality and Thinking which tackles the abstruse problems concerned with consciousness, self awareness and naturally disorders of both

Anyone reading this Introduction seriously will find that in acquiring his first formal background in Psychology he will also have to think at times like a physiologist, a philosopher, an anthropologist and a good experimental scientist all rolled into one. This will turn out to be less complicated than one might imagine.

II PERCEPTION

(a) Information Gathering and Information Decoding

The topic of perception itself breaks down into two significantly different headings and it is very important to comprehend the distinction between the two before going any further. These are the processes of *information gathering* and *information decoding*. If these words seem a bit bothersome they need not be. Information has a meaning in science rather broader than details of train times or facts from history and it really deals with the influence of one object, person or thing on another. For example, when you look at the sun or a bright light photons from the luminous object strike the retina or sensitive layer at the back of the eye. As the result of this the retina changes its state slightly and in due course passes signals back to the brain. Now the exchange between the sun and the retina odd though it may seem at first constitutes an exchange of information and when the message finally reaches the

brain and the sun is recognised for what it is the information has flowed all the way from sun to brain. If this appears to be an odd use of the word information then this is probably because one has tended to think that information can only be conveyed through words or numbers and meaningless conversations. The more one thinks of this limited point of view however the less reasonable it seems. If one looks at a painting which contains neither numbers nor words but a picture of say a ship at sea then most people will agree that it is conveying information (the artist originating it whenever he painted the picture). In fact we can use this analogy to add that the painting itself can be looked upon as a kind of information store since the artist who set the whole process going could easily be dead and gone and yet his message continues to be conveyed. If one no longer feels it inappropriate to talk of the sun as an emitter of information to the eye then we have made a major advance and can move on into the meat of this sub section. It is really important to get some grasp of the scientific use of words like information and information storage for they will pop up time and time again and one can make nothing of modern psychology without them. Incidentally when we spoke of the retina sending signals up to the brain where the sun was recognised it should be remembered that what reaches the brain is not a kind of miniature sun but rather a pattern of impulses which need to be interpreted. This interpretation we call information decoding and it is the second important factor in perception which we will come to shortly. But first how is the information received and gathered?

(b) The Five Senses

Simple creatures such as amoeba react in a vague generalised way to objects in their environment. The reason for this is that they have no specialised equipment to allow them to detect what is taking place or about to take place around them and no computing centre capable of selecting alternative modes of behaviour. As we ascend the evolutionary scale from jellyfish to worms and up through reptiles, mammals, birds etc. we note increasing specialisation of the body's cells, the development of devices capable of scanning the external environment and increasingly complex co-ordinating nervous centres (brains). By the time we reach Man and other advanced animals the individual is not merely reacting to his environment but consciously aware of it, able to predict many of its changes before they can affect his body physically and frequently manipulating it significantly to suit his own ends. This immense versatility is dependent upon information from the environment being fed into the nervous system for processing and the devices which the body has developed to gather this information are known as the senses—vision, hearing, touch, taste and smell—roughly in order of importance. Without these senses the interface between the central nervous system and the world outside a living creature is nothing more than a helpless vegetable incapable of survival. For this reason if we are to get anywhere with understanding the operation of the brain we will need to know a fair bit about the sense organs that feed it. We shall spend most time on the two most important—vision and audition.

(c) The Eye

Perhaps the most useful information from the brain's point of view would be that which concerns the detection of food or a mate at a distance or of course the presence of danger in the form of a predator. Consequently the most vital and remarkably developed of our sense organs are our eyes which are geared to detecting radiation over a frequency range which we call light. For those who like this kind of detail, the actual spectrum detected by the eye covers light frequencies whose wavelengths range from about 380 millimicrons to about 720 millimicrons. All this means is that the distance from peak to peak of the waves which constitute the light is a very small amount indeed—far less than a thousandth

of a millimetre in fact. Note however that not only can the eye detect the 380 and the 720 millimicron waves quite easily but it can also discriminate between them and a whole lot of other wavelengths in between as well. In fact we call the 380 mμ waves violet, the 720 mμ red, those of about 500 mμ green, etc. Remember the minute frequencies involved and you will appreciate that whichever part of the eye handles this kind of information must be very sensitive indeed. This fabulous bit of equipment one of the most remarkable of all biological systems is called the retina.

The Retina

Situated in a layer at the back of the eye the retina is a kind of screen on to which rays of light are focused by the lens after having passed through a window at the front which is called the cornea. The question now arises as to how the retina detects the light rays and how it then signals the relevant information on to the brain. There are two ways of answering this question one very complicated and reasonably accurate the other quite simple and slightly less accurate. We'll choose the simpler and lose a bit of accuracy without worrying too much.

The principle employed is that of energy absorption. The retina is a densely packed mass of neural cells whose speciality is that they contain light sensitive substances known as pigments. These substances change their state rapidly when the photons from a light source strike them and this change which is really a high speed chemical reaction acts as the trigger which fires the cell. This in turn sends a pulse of electrical activity up the neurone's long stem in the direction of the brain. After it has fired the cell then requires a brief period to recover its normal state and for the minute portion of bleached pigment to regenerate during which time (known as the refractory period) it will not fire again. Multiply all this by one hundred million which is the approximate number of cells in the retina and you will get some idea of the frenzied activity contributing to the process of vision. To complicate matters there are at least two major types of visual receptors the cones and the rods. To go into their infrastructure in detail is really the province of physiology but it is necessary to know something about their prime function which is that the cones tend to handle the higher levels of luminance met in daytime and also mediate colour vision while the rods which are far more sensitive tend to come into life in the dusk or dark. The shift from cone to rod vision which like most of the body's basic functions is entirely automatic is something we all experience regularly in our daily life. Walk out of the sun into a dark room and for a moment one is blinded. Walk out of a dark room into the sun and again one is blinded! Actually all that is happening is that the visual system is having to shift from one set of receptors to another and when the change is extreme and rapid the lag in the switchover is dramatically apparent.

Colour Vision

Psychologists have known for a long time that the cones which tend to be packed in the centre or more useful part of the retina have something to do with colour vision but just how they do this job has been a matter of much debate and argument. One of the most likely bets would seem to be that particular types of cone are equipped with particular types of pigment one sensitive to light in the red range another to light in the yellow another in the blue etc. But how many types of cone would one need therefore to get the kind of colour vision we enjoy? Would one have a separate type for each subtle shade of hue for example? When thinking such things out scientists always try to see first if they can get by with the smallest possible number of hypothetical elements and only bring in extra mechanisms when they are absolutely stumped—a principle known as Occam's razor and one universally revered in science and philosophy. With this in mind and with a bit of ingenuity the general view at the moment is that

three separate types of colour receptor are all that are needed to account for human colour vision. This is known as the trichromatic theory which is all we need to know about it for the purposes of this article. But just to show how complicated things are and yet how interesting for this very reason we will pause to look at some experiments in human colour vision which show that no matter how neat and simple an explanation is in psychology there is always a joker hiding in the pack.

Some Experiments in Colour Vision

To understand these experiments which were performed by a Swiss psychologist, Dr Ivo Kohler we need to know a little bit about the phenomena known as after images. This information will come in handy again a little later on when we talk about after images in a slightly different context. You may have observed that if you look at a bright light for longer than a second or two when you close your eyes you see a continuing image of the object which may persist for quite a while and exhibit a nice range of rather bright colour changes. If you haven't observed this then you can experiment yourself by just fixing with one eye on the filament of an electric light bulb—not too close to the eye. Count five slowly as you do so then close your eyes and observe. (Don't do this with the sun by the way as it could be dangerous.) Now the important point at this stage is the changes in colour you will see taking place which are generally believed to occur because the bright light has slightly overbleached the retinal pigments and they are taking longer than usual to recover. In the process of recovering they continue to send signals to the brain which interprets this information as if there was still a light source present and thus the bulb filament is seen long after it has really gone. The colour changes themselves are probably due to the fact that some pigments regenerate a bit more quickly than others and thus a sequence of colours is perceived. All this involves lights of greater than average intensity and the question is whether one could get after images with low intensity objects looked at for a long time. The answer is yes and for anyone who hasn't noticed this before another simple experiment can be tried. Take a book with a brightish colour binding—say red. Fix on it with one eye trying to keep your head and eye as still as possible and hold it for about one minute. Now turn the head away from the book and look at a blank, light wall or other flat surface. What one will see is a rather amorphous image of the book, but coloured green which will linger for about half a minute before it fades away. This is another version of the first trick, with the after image being due to the bleaching of the red pigment and to various other changes that follow in its wake. Now the after image as we have noted soon fades away and no doubt this has something to do with the intensity of the original stimulus. But what would happen if instead of merely exposing oneself to the colour for a minute or two one extended the time period to an hour or a day or a week or even longer? This is exactly the question that Kohler set out to answer. To get over the problem of how one could possibly go on looking at something for hours or days on end he decided on the simple expedient of wearing tinted spectacles and going about his business as usual. For the first experiment using pink spectacles, he wore a number of interesting discoveries. Number one was that although for the first few hours in his experiment the world took on a rosy hue before the first day was over things were nearly back to normal. After a few days there was no longer any suggestion of a more than normal amount of pink about and his vision appeared to be unaffected—even though of course all light was being filtered through the red lenses and thus inevitably tinted. Discovery number two came when he finally took the lenses off to find the whole world tinged with green—the so-called complementary colour of red—a tint which remained for days! His next experiment apart from doing the whole thing over again with a different set of colours—blue lenses providing a yellow world green a red one etc—was to wear spectacles with one lens

red and the other green. This time the position was more complicated. If he closed his right eye which had the red filter in front of it then he saw green through the other lens and vice versa. With both eyes open however the two colours would mix in his brain and the world appeared through a kind of blue haze. At this point you might care to try to predict what the scientist found when after a few weeks of this and after all the colour had washed out, he finally removed the spectacles. In the first place if he looked at the world through both eyes he saw the complementary to blue (which is yellow) but if he looked through either of his eyes singly he saw the world tinted with the appropriate complementary colour red or green. Once again the new tints took some time to disperse. All this of course while exceedingly interesting could still be reasonably explained on the theory of pigments bleaching away due to long exposure and taking some time to regenerate. Unfortunately for this simple idea, but fortunately for people who like problems, Kohler's next experiment produced a surprise result. For this he had the ingenious idea of segmenting his spectacles so that the right half of each lens was tinted red, the left half green. The position now was that if the wearer looked to the right with both eyes he saw a red tinted world if to the left a green tinted one. Looking straight ahead produced a muddling fusion of both colours. In due course as one might predict, all spurious colours washed out wherever one was looking. Now came the surprise. On removal of the spectacles Kohler found that when he looked ahead he saw the complementary fused colour but when he looked to the right he saw the complementary of red which was green. When he looked to the left he saw the complementary of green which was red. To work out why this was surprising one must think about what was happening in the retina. In the early experiments with the whole of the right visual field tinted red, say the persisting perception of the green after image was felt to be due to some changes in the pigmentation of the cells in the retina. But clearly this will not do in the final experiment for in this case the same areas of retina seem to be doing two different things. After the glasses had been removed when the subject gazed to the right he saw a green field and one might assume that this was because the pigment had been changed by overstimulation. But how could this account for the fact that when the subject turned his eyes to the left there was a change of perceived colour to red? Clearly the pigment itself couldn't have changed in that time nor could it change back when the eyes reverted to the left. Obviously quite contrary to what one might expect, the colour changes were dependent in this case not on the state of the retina but rather on the direction of gaze!

No one has satisfactorily explained Kohler's intriguing results to date but they do suggest one important point which one is always in danger of neglecting in psychology—that a living organism is not just a collection of parts acting independently of each other. In the drastic situation of wearing tinted lenses for days or even weeks, changes were evidently taking place not just in the retina of the eye but also in higher centres of the brain.

More About the Rods and Cones

Returning briefly to the retina and its constituent cells we might just take a closer look at the rods which you will recall come largely into play in conditions of poor luminance.

The extraordinary sensitivity of the rods is the most interesting thing about them. Unlike the cones which need the brightness of daylight to do their justice, one single rod will be triggered into action by light whose energy is as low as 10^{-14} ergs and if that is a value which has no meaning one can get a graphic idea of this sensitivity when one learns that in total blackness the eye could detect the light of a single candle five miles away! Put another way the amount of kinetic energy used in lifting a pea one inch would, if converted to light energy be enough to give a brief sensation of light to every person that has ever lived on earth! The clustering of cones in

the centre of the retina the fovea has been mentioned and the rods consequently tend to be scattered around in the periphery. You can detect this geographical distribution yourself by noticing that whereas in daytime your vision is much better directly in front of you in very dim light you will be able to see objects on the edge of your visual field rather better. You must also care to note how the periphery of the retina is populated largely by rods and devoid of cones is remarkably insensitive to colour. Offhand one gets the impression that the whole of one's visual field is richly endowed with colour but this is far from true. A simple experiment will demonstrate this. Fix with one eye closed on a pre-determined spot—a mark on a piece of paper will do. Then slowly bring into your field of vision from the side a small piece of coloured paper drawing it closer and closer to the central spot. Now if you can manage to keep your eye really still and maintain fixation despite the tendency to peek at the incoming paper, you will be surprised how far in the latter will have to be before you can detect its colour with certainty. Try the experiment again with another colour and note that it may be recognised earlier or later. In this way it is possible to plot a simple map of one's own retina defining the boundaries of the colour sensitive areas and nicely illustrating the division of retinal receptors into two distinct types with different jobs to do—the rods and the cones.

(d) Perception as a Dynamic Process

Everything we have said in this particular section has reinforced the idea that creatures with complex brains are something far more than automata responding blindly to changes in the environment. Information fed in through the eyes etc. is processed in some way by the brain, or decoded, as we put it earlier. In fact it is this business of decoding and the possible mechanisms which help to achieve it that interest psychologists more than the raw details as to how the senses actually gather the information in the first place. Nevertheless until relatively recently there was a school of thought in psychology that made desperate attempts to deny or at least reduce the role of a central integrating process implying that animal and human behaviour could ultimately be reduced to a great mass of stimulus response networks triggering each other into action in a totally mechanical fashion. This

Behaviourist school as it was known, had more impact on theories of learning and we shall look at it more closely when we come to the appropriate section but it also influenced the thinking of psychologists interested in perception. The trouble with this point of view is that it is so obviously inadequate to explain the rich material of perceptual experience. One has only to think of the visual illusions that are experienced when information correctly relayed from the eye is misunderstood or incorrectly decoded in the brain itself. Look at the visual illusion reproduced on the back of the jacket where two lines which appear to be slightly bent are objectively parallel. Clearly it is enormously interesting that all human beings fall prey to illusions for it suggests that some common mechanism exists which is causing them.

The Gestalt Approach to Perception

Among the first people to take this up as a general principle and use it as a frontal assault on the Behaviourist view was the so-called Gestalt school of psychology founded in the early part of the century by three talented psychologists: Kurt Koffka, Wolfgang Kohler and Max Wertheimer. In point of fact they looked more closely at other common features or anomalies of perception than at visual illusions, for they believed that the introspective and experimental analysis of human perceptual experience allowed one to deduce the laws of perceptual organisation and that these laws must throw light on the fundamental operating procedures of the brain itself. A simple introduction to Gestalt theory is given in Section J so we will confine ourselves here to looking at a few of their more important

ideas most of which are still valid in modern psychology. The first was their insightful statement that in perception the *whole is something more than the sum of its parts*. This principle is nicely illustrated by the fact that a series of dots drawn fairly close together in the shape of a ring are perceived as having a very definite form — i.e. that of a circle—despite the fact that all one has actually put on a paper is a collection of dots. Dots are all that are perceived by the retina and the signals passed up to the brain can only be those arising as the result of the dot stimuli. Look at such a picture however and one sees a circle. But where does this come from? From the brain say the Gestalt psychologists pointing out that the whole (i.e. the perception of the circle) is something over and above the sum of its parts (i.e. a collection of points or dots). The same thing can be applied to lines or practically any other shape and can even apply in the auditory sense (a tune is something over and above a collection of separate notes played in sequence). The Gestalt school argued that this was clear evidence for the existence of dynamic forces in the brain whose function was to mould or *structure* the information as it was fed in by the senses. Further examples of this structuring could be seen in other types of visual phenomena and Koffka and his colleagues formulated a number of laws of perceptual organisation which they held were universal and also probably innate or built into the brain at birth. These laws are a bit too involved for us to discuss in detail but one or two are worth mentioning because the reader can conduct simple experiments for himself. The first known as *Continuity* is a rather obvious one and similar to the example of a dotted circle that we had earlier. This states that a collection of dots arranged so that they form a continuous line whether straight or curved would tend to be perceived as a *unit*. In other words structuring forces within the brain tend to act upon such dots causing them to be perceptually linked despite the fact that they have no true continuity in the physical sense. The age old perception of the constellations in the sky formed out of near random stellar patterns is a good example of the law of *Continuity* in action. Another important law is that of *Similarity*. To observe this in operation scribble on a sheet of paper about twenty small crosses at random. Now among these crosses again scribble down about 10 small circles. Look at the composite picture and you will probably note that the circles more or less wherever they are tend to stand out in isolation from the crosses—the law of *Similarity* in operation. Obvious? Maybe—but why *should* similar things stand out against a dissimilar background? Obviously some important factor in perception must be at work. Yet one more Gestalt law that of *Closure* is worth mentioning because its operation is easy to observe experimentally. Koffka and his colleagues believed that the perceptual organising system tended to dislike incomplete or partial figures and where possible would close them. This was particularly true they argued with neat simple figures such as circles triangles etc. To illustrate this draw a small neat circle on a piece of paper but leave a small gap in it say about a tenth of its circumference. Now close your eyes and open them very briefly to give yourself a fleeting glimpse of the figure you have drawn. The chances are that what you will see is a circle without the gap. Try this on someone else who doesn't know that there is a gap present and it will work even better. Now one might reasonably argue that one has missed the gap because one didn't have time to see it but that's really no explanation as to why one should see a *complete* circle. The Gestalt argument is that in such fleeting glimpses the law of *Closure* within the brain overrides the rather feeble information about the gap that comes up from the retina and the result is the gap just never gets perceived. The effect incidentally works for longer looks at patterns viewed in dim light.

A good deal of controversy surrounded the Gestalt approach to perception much of which has died down in recent years as the Gestalt point of view has gradually fallen out of favour. One of the most controversial facets of the theory was the belief that the so called laws were innate or

present at birth. In other words if one could somehow question a new born baby and get a sensible answer out of it we would find that it too had its perceptions modified according to the Gestalt laws of *Continuity*, *Closure* etc. And this brings us to the very interesting question of just what it is that babies can see at birth—if anything.

(e) Learning to See

Anyone who has spent any time with very young babies will realise that their powers of perception are at best poorly developed. The mother may feel greatly flattered at being recognised with a smile but the harsh facts are that a young baby will produce a charming smile for practically anything—even an absolutely horrific mask—that's placed in front of it. The psychologist William James (brother of the novelist Henry James) actually stated that the world of the newborn baby was a buzzing booming confusion—in other words a mass of sensory data rushing up to the brain with nothing up there to interpret it. This is probably close to the truth—at least as far as human babies are concerned for there is very good evidence that babies do not come into the world equipped with the ability to perceive the environment in the orderly clear cut way that adults do. Incidentally this is not due to any deficiency in their visual system for the new born eyes are physiologically mature with at least the *potential* for detailed colour and pattern vision. What seems to be happening is that in the first few months perhaps years of life young humans literally have to *learn to perceive* as the brain gradually acquires the power to integrate the information sent up by the senses into a meaningful picture of the environment. There can be no better illustration of the vital distinction psychologists draw between vision (or audition for that matter) and the act of *perception*. One concerns itself with input the other with its interpretation. Now with animals it is a different story—some what. Among the primates chimpanzees monkeys etc perception at birth is better than with humans but still pretty uncertain and the lower down the animal kingdom (this is called the phylogenetic scale) one goes in general the better the creature is equipped at its birth to perceive the environment. Look at it another way and say that the simpler the creature and the less well equipped with cerebral cortex the more wiring or circuitry is built into it and carried over to every member of the species. This of course is what is meant by instinct—an inherited behaviour pattern or function of some kind which appears in every member of a species at birth. See also F38(1).

Instincts are very useful in one sense since the creature endowed with them doesn't have to learn the instinctive task and can perform it at birth (suckling is one of the few human instinctive reflexes). On the debit side however is the fact that one can't *unlearn* the instincts either so that the more of them one has the more likely they are to get one into trouble if one is a creature likely to change its environment in any radical way. Think for example how powerless human beings would be if they were subject to an instinctive desire to hibernate for six months at the onset of each winter. Clearly instincts are good for creatures with limited cerebral capacity but a big handicap if one wants to respond in a flexible way to the world around one. The big question now is does the ability to perceive develop as a natural consequence of the maturing brain or is it dependent upon practice and experience?

Some Investigations

If one takes kittens and brings them up in total darkness for say a month on being subjected to the light they seem to have normal perception—pretty well equivalent to that of kittens normally brought up. However if one extends the rearing in the dark for a much longer period say a year then the young cat never seems to achieve normal vision on its introduction to a lighted world. Post mortem examination of the brain reveals that certain parts of the visual system seem to

have failed to develop in the normal way. Evidently there is a critical period which when exceeded without visual experience stultifies the brain so that normal perception can never be achieved. But what of humans? This may seem an impossible question to answer for how could one conduct the necessary experiment—i.e. deprive new born babies of light for up to a year—without outraging all moral and ethical values? In fact by an odd and fortunate twist the necessary data has come to us without the need to perform an impossible experiment. In the 1930s new techniques of surgery allowed the performance for the first time of an operation to graft the human cornea. This you will recall is the transparent window on the front of the eye which can with age or disease become clouded and opaque. Occasionally the cornea may be opaque at birth with the result that the individual can never achieve the perception of patterns or shapes. Because some light is getting through the milky window however he may be able to tell the difference between say periods of light and dark. Prior to the 1930s people afflicted with clouded corneas were consigned to a life of effective blindness—the more tragic because in all essentials they were frequently equipped with perfectly operating retinal optic nerve etc. With the development of corneal transplant surgery the picture dramatically changed and while the operation is now usually performed at a relatively early age there was an initial group of people in middle age waiting to be treated who had *never had normal vision*. Realising that this provided a unique opportunity for an interesting observational study the German psychologist Von Senden arranged to follow the progress of the patients with new corneas and record their reactions to the sight of objects which they had hitherto only heard described. Von Senden was set for some surprises—but nothing like the ones that he got. In the first place the newly sighted patients, far from gazing round in wonder at the marvels of the visual world were apparently totally incapable of making any sense out of it! This was not incidentally a mere failure to recognise subtle differences such as exist between people but a totally inability to tell the difference between most common everyday objects. Showing the patients large simple drawings such as a triangle and a square naming them and then switching their relative position would totally confuse the patients. In order to tell the difference they would have to laboriously trace the outlines of each figure carefully counting the corners. Notice that they could *see* the outlines corners etc.—their eyes were functioning properly—but they were unable to perceive the pattern. Their brains were simply not equipped to recognise shapes and like young babies they had to learn the whole process slowly and laboriously. Von Senden's second surprise came when he found that few of the patients seemed to find at least in the early stages the gift of sight at all welcome. Some in fact literally begged the doctors in the hospital to replace the bandages over their eyes! As with young babies their visual world was indeed one of a buzzing booming confusion and it took some going used to. There's a happy ending to Von Senden's story. All patients in due course acquired the ability to perceive slowly at first but with increasing speed and confidence.

The moral of all this is clear and once again emphasises all the points we have been trying to make about perception. The brain is a device designed to integrate information fed into it by its senses. In due course this integration becomes almost automatic but this is reached only after a long period of training which in humans occupies the greater part of infancy and early childhood. How much is actually built into human brains at birth in the field of perception? Probably very little if Von Senden's work is accepted without reservation. Unfortunately there's some curious contradictory work to muddle the issue (as usual) and it concerns experiments with young babies performed by the psychologist J. J. Gibson. His strategy was to take infants and get them to crawl towards what he termed a *visual cliff*. This consisted of a sheet or strong glass placed across a kind of trench or ditch in the laboratory the bottom of which was lined with a chequer

pattern. The children were tempted to cross the trench to come to their mothers, this of course involving their venturing out over the glass sheet. Adults might naturally hesitate slightly pondering perhaps the strength of the glass and the depth of the pit below it. Young babies would of course know nothing of the fragile nature of glass, go should not be worried by that. Nor if they were not equipped with proper pattern recognition mechanisms should they be able to appreciate the depth of the pit or the nature of the visual cliff they would have to cross. Gibson found however that all children showed exceptional caution when reaching the cliff point and many could not be tempted into apparently empty space. Common sense? Perhaps, but either they have the perceptual mechanism for they don't and in this case it looks as though the perception of depth and even some kind of appreciation of the gradients involved in the cliff were at least present in the babies capable of crawling. Does this contradict the work of Von Senden? Not necessarily—perhaps certain vital things (such as the ability to recognise a steep slope) are instinctive in humans while matters such as the perception of patterns like faces triangles squares etc. need to be learned.

(1) The Building Blocks of Perception.

To this point we have been considering (i) how the information is fed into the brain and (ii) the evidence for the fact that dynamic integrating forces act on this information to mould it in specialised ways. We must now try to consider how this processing might take place. In what ways what actually happens inside the brain when a particular pattern or shape is recognised?

Investigation of Individual Nerve Cells

To get some insight into this we need to take a closer look at one of the latest techniques for studying the brain which we referred to earlier and which is known as microelectrode recording. The principle here is to insert an exceptionally fine electrode into the cortex of an anaesthetised animal endeavour to place it against the body of a single neural cell and then via a suitable amplifying system, record the pattern of electrical activity given off by the cell. This technique which was developed in the 1950s represents a significant advance over that of electroencephalography (the recording of brain waves from outside the head) inasmuch as instead of being faced with a rather vague pool of electrical activity possibly coming from numerous cerebral sources one is able to study the responses of what must surely be the brain's fundamental unit the neural cell. Studied in this way the activity of a single cell is very interesting. Firstly cells appear to have no period of total inactivity—whether the creature is sleeping or waking and whether stimulated or not single cells keep up a steady periodic burst of firing at an average frequency of one burst every few seconds. This has acquired the name of spontaneous activity which is another way for saying that psychologists and physiologists don't know what causes it. In the normal living brain therefore, even when the creature is in a totally relaxed state, millions of cells are bursting periodically into action a continuous background of electrical noise. This presumably signals the presence of life itself for only with the death of the individual do the brain's cells cease their restless firing. When the animal is stimulated in some way by light noise heat cold etc. then measurable changes take place. If the stimulus is visual cells in the visual cortex of the brain burst into life while those in areas subserving other senses remain at their spontaneous level. Introduce auditory stimuli or mixtures of other stimuli and cells perk up in the appropriate areas of the brain. All this is very much as one might expect backing up our knowledge that different sections of the cortex handle different tasks. But can one focus down rather more sharply? What happens if one studies the behaviour of cells within only one area of the cortex when different stimuli mediated by the same sense are fed in?

This experiment was first performed by the American physiologists Hubel and Wiesel with remarkable results. First they located a cell in the visual cortex of the cat and began to record the output from it when the cat was shown a variety of visual patterns. At first the cell merely exhibited the normal background firing but when the cat was shown a luminous vertical line the cell suddenly burst into frenzied life. In the meanwhile other cells in different parts of the visual cortex continued with only background firing. When the vertical bar was slowly rotated so that it was tilted on to the diagonal the first cell gradually relapsed into background firing but in the meanwhile another cell began to increase its firing rate. This too switched off when the bar was rotated again to a new angle while yet another cell sprang to life. In this way Hubel and Wiesel in a memorable series of experiments in the 50s and 60s began to systematically plot the cat's visual cortex noting over and over again the fact that individual cells seemed to be specially labelled to respond only to specific stimuli. The same applied to cells in the auditory cortex and even—though these were much harder to track down—in other sensory areas. In homely terms what the two Americans had done was to isolate the building blocks of perception the terminal points in the brain where information being fed in was categorised or classified and where the amazing process of pattern recognition was actually taking place. Similar experiments were soon being performed with a variety of animal species and also with a range of ages from the infant animal to the totally mature. Here again evidence seemed to imply that with animals higher up the phylogenetic scale these perceptual units tended to be learnt rather than built in for they were clearly present in the very young animal or the mature animal which had been experimentally deprived of normal environment.

Recent Experiments on the Human Perceptual System

All this tells one a good deal about the animal brain but can one make the bald assumption that a recognition system of this kind exists in humans as well? Microelectrode recording with living humans is probably out except in certain rare surgical cases so one might expect this to remain an academic question for all time. However by one of those happy chances which favour scientists from time to time some recent experiments performed in England suggest that the human perceptual system *does* work along lines similar to that of the animals. These experiments involve a technique which has the rather daunting name of the stabilised retinal image but which is a good deal simpler than it sounds at first.

To see the significance of this one needs first to appreciate the relationship between movements of the eyes and the image projected on to the retina. Looking directly at a pattern of some kind as we have learnt leads to an image being focused on the retina at the back of the eye much as an image is projected on to the film at the back of a camera. Now suppose that the pattern instead of remaining stationary moves across the visual field the image of the pattern moves correspondingly across the retina. Conversely if the object remains fixed but one moves one's eyes then the image is again displaced across the retina. Well what happens if the object remains absolutely stationary and one keeps one's eyes fixed carefully on it? Does the projected image then lock solidly on to the retina? The answer is actually no but for no reason more peculiar than that it happens to be physically impossible to keep one's eyes absolutely still. No matter how hard one tries the eyes continue to move in a feeble trembling motion, barely detectable without specialised instruments. Inevitably the image of any object in the visual field trembles rapidly on the retina at the same time. This might seem to make vision rather imprecise and blurry but for reasons we haven't the space to go into this tremor actually serves to *improve* vision—in particular the kind of super detailed vision which allows us to see minute specks or very fine lines such as spiders' cobwebs. For some time psychologists have been curious about what would

happen to vision if these fine eye movements did not exist but since they are quite involuntary and automatic the task seemed pretty hopeless. Then someone—the physicist R. V. Ditchburn—had the bright idea of tackling the problem from a different viewpoint. He simply wore a contact lens (which of course acts like a new outer layer to the eye) with a short stalk sticking out of the front of it. On the end of this stalk he fastened a little photograph and a lens to focus the image sharply on the retina. By this trick he had effectively cut out the effect of all movement made by the eye great or small because wherever the eye moved now so the contact lens followed it and the stalk and photograph followed it too. If you think for a moment you will realise that this means that the projected image of the pattern remains in one position on the retina—the stabilised retinal image. (If you find this difficult to visualise try sketching the system on a bit of paper—eye contact lens stalk pattern and of course image on the retina. The logic will immediately be apparent.)

With this system Ditchburn made two very interesting observations. Firstly the stabilised pattern disappeared thus suggesting that the fine eye movements were essential to visual perception. Secondly he reported that when a pattern disappeared it frequently did so *in part* rather than washing out as a whole as one would rather expect. Furthermore the parts that came and went tended to be neat even sections of the pattern. For example a cross would alternate between the vertical and horizontal bars a triangle would break up into one or other of its three sides etc. A number of experiments have since been performed with human subjects using this ingenious and unusual apparatus with results which suggest to psychologists that they are dealing with the same kind of perceptual units Hubel and Wiesel found in the cat. The tendency of the lines to appear and disappear as units when viewed as stabilised images seems to imply that basic line units are also present in the human brain—the building blocks of perception again.

It so happens that these fascinating fragmentation effects can be observed by a simple experimental method which does not involve wearing specially fitted contact lenses. You will recall that we spoke earlier of after images which are temporary changes in the state of the retina caused by a bright light and these are of course perfectly stabilised images since they are part of the retina itself. To observe them oneself the best trick is to sit in a rather dark room and stare at the window frame against the bright sky outside. Do this keeping one eye closed and the other as still as you can manage for about thirty seconds. Then close both eyes and *keep them closed*. After a second or so you will see a vivid after image of the cross pieces of the window frame and you will note that the vertical and horizontal bars of which it is composed come and go independently of each other. This is some thing far more than a trick incidentally—as you do it you will be watching your own brain at work processing the pattern locked on to the retina.

We have spent a good deal of time on vision and visual perception because (a) it is easily the most important of the sensory channels and (b) because it is the area of perception best charted by psychologists and physiologists. We will now take a less detailed look at the other senses.

(g) The Ear

The eyes as we have learnt are equipped to detect visual radiations within a fantastically fine bandwidth—less than a thousandth of a millimetre. From the brain's point of view this takes care of a good slab of some of the most important sources of energy and radiation within the universe but a brain equipped only with eyes would be blind to a good deal of important information. Therefore we find a complete set of specialised receptors handling other areas of interest, of which by far the most important are the ears. These are tuned to pick up waves and vibrations too but of air waves rather than light and in an entirely different range. The absolute

spectrum to which the human ear responds is between about 20 and 1,000 cycles a second with a peak sensitivity between about 1,000 and 6,000 cycles per second. All sounds we can hear therefore consist ultimately of vibrations of the air occurring within this frequency range and in the case of human speech we are dealing with a complex pattern of such vibrations. The ear's method of detecting these and translating them into an electrical code is ingenious and enormously efficient.

Auditory Perception

The process begins with the outer ears (the flaps of skin on the side of your head!) which serve to catch sound waves coming from the most important direction in which in the case of human beings is in front of them. The importance of these directional indicators is considerable and you can note how strikingly you can change your own auditory perception by flexing the ears with your hand or cupping your hands so that the directional indicators point backwards. Once channelled into the innards of the system the sound waves are forced down an ever narrowing tube where they come up against something called the tympanic membrane which is better known as the eardrum. Popular belief seems to be that the auditory process stops here but from what you have learnt already you can work out that there will need to be much more than this. The translation of the physical vibration of the eardrum into electrical signals will have to take place. In fact the vibrating drum itself sets into motion a beautiful percussive machine in miniature three tiny and elegant bones known as the hammer anvil and stirrup which carry the message deeper into the ear where they come up against yet another drum. This is the gateway to a spiral tube called the cochlea which is filled with a densely packed fluid and the walls of which are lined with hundreds of thousands of tiny hairs. As the last of the bones in the tiny percussive link beats up against the fluid inside the cochlea it sets up a series of rapid shock waves which in turn induce complex patterns and rhythms of movement in the hairs linking the cochlear wall—rather like the shifting waves of motion that the sea induces in forests of seaweeds only on a faster time scale. These hairs are themselves hooked up to auditory nerve cells and in some way at present uncertain to psychologists and physiologists specific movements of the hairs tend to activate specific cells the end product being that a series of complex but significantly different patterns of electrical activity make their way up the brain. Here the auditory centres get down to the business of interpreting these electrical signals into meaningful sounds.

Thinking of the immense sensitivity of the hairs in the cochlear fluid it may have occurred to you that it ought to be possible to set them in motion by almost any kind of external vibration—and thus hear without vibrating air waves having moved into the ear. This is quite true. Sound waves can be transmitted through other media than air including bone and thus even if the ears are blocked one can hear certain sounds remarkably well. Try it for yourself and you will note that the quality of your hearing changes markedly—your own voice for example will sound deeper and barely less loud yet if you whisper you will not hear yourself at all. The reason for this is that with ears blocked the sound is being propagated to the cochlea by bone conduction and thus acts as a filter cutting out the high frequency components almost totally but letting in the lower notes without too much trouble. This is why earplugs are disappointingly ineffective.

This is probably enough about the ear which if the truth is known is rather less well understood by psychologists than the eye. Only one major point might be briefly touched on. Why do we have two ears rather than, say, one large one on the top of our head? The answer is that a binocular system allows us to locate sounds rather better slight differences in the time it takes for sounds to reach each ear (as when one ear is slightly closer to a sound source) cause fractional delays in the arrival of the respective signals to

the brain—enough for the magnificent computer there to deduce the sound source's rough location.

(h) Smell Taste and Touch

Olfaction

Of the remaining three senses only one is concerned with detecting objects at a distance after the fashion of vision and audition. This is olfaction or as we generally call it the sense of smell. Olfaction is particularly interesting because it is concerned with the detection of chemical substances in the air rather than with wave or vibration analysis. Animals of all kinds make much use of their ability to recognise the chemical changes taking place in plants other animals etc which serve to indicate good (i.e. necessary for survival) or bad (i.e. dangerous) objects. These may range from the sweet smell of edible fruit, the characteristic odour of a mate in a sexually receptive state or the nauseous smell of rotting flesh riddled with dangerous bacteria. Unlike vision and audition the olfactory sense mechanism is relatively simple in form consisting of two small patches of cells situated rather high up in the nasal passages and not in the main line of breathing. This accounts for the animal habit of sniffing to detect smells better the sniff being a method of pushing air up into the rather inaccessible smell receptors. As with pretty well everything else in the body the olfactory receptors are specialised nerves immune of course to light or air vibration but unworldly, quick to react to a wide range of airborne molecules. The presence of particular molecules on a receptor causes a chemical change to take place in the cell this in turn inducing an electrical signal to pass up the olfactory nerve. Psychologists have not spent too much time on this sense for it seems to be of relatively low importance to modern man but have pondered the interesting question as to just how many different kinds of smells human beings can detect. You might try to think about this for yourself and before you say hundreds you should realise that most smells like most colours are probably mixtures of a relatively small number of primaries. There is as it happens no definite agreement as there is on the seven colours of the visual spectrum but an early classification by the psychologist Findley in 1934 has probably not been bettered. His smell prism listed six primaries which you may like to compare with your own choice. Each smell is identified with a substance which Findley thought was a typical generator of the odour: (1) fragrant (oil of jasmine), (2) ethereal (oil of lemon), (3) resinous (turpentine), (4) spicy (cinnamon), (5) putrid (hydrogen sulphide or rotten eggs) and (6) burned (oil of tar).

Taste

We now move from the distance senses to the so-called proprioceptors which is the name psychologists give to the senses concerned with the detection of things actually in contact with the body. Although it is not classed in this way the logical one to look at next is taste which has much more in common with smell than most people imagine. Taste in itself is a rather feeble sense mediated by a number of chemically sensitive receptors on the back and sides of the tongue and the relative overemphasis of its importance is due to the fact that when people talk about great subtleties of taste they are generally talking about great subtleties of smell for the latter is vital in any gastronomic treat. The simplest test of this is to sample some particularly good tasting substance savour its flavour and then hold one's nose. The reduction in taste is dramatic and one can soon realise how a bad head cold can have such drastic effects on the enjoyment of food and drink. One other remarkable feature of the sense of taste is how quickly it adapts out—a drink which tastes sweet or sour at the first taste slips into bland neutrality before the glass is emptied. This is another experiment the reader can surprise himself with particularly if he holds his nose while drinking thus eliminating the vital smell component. The classification of tastes is somewhat easier it seems than that of

smell with most psychologists settling for four primaries with which you will probably find yourself agreeing—sour, salt, sweet and bitter. Anyway the plain fact is that the gustatory sense is a very limited tool in mankind's sensory workshop and poses few experimental questions.

Touch and Sensitivity to Pain

The remaining sense that of touch includes under its heading a good deal of sub-senses such as the detection of pressure, heat, cold and the highly enigmatic pain. Pressure, heat and cold are fairly well understood, probably being mediated by a number of different types of specialised cells embedded in the skin. Much controversy surrounds the number of different types of receptors involved and the matter is complicated by the fact that no one has positively identified a pain receptor—one which fires only when a potentially dangerous stimulus contacts the body. An early view held that pain was simply the signal the brain received when any kind of stimulus was excessive but for a number of reasons this will not do. There are also some peculiar factors such as the observation that it is not all that easy for a person without any other cues to tell the difference between hot and cold objects. Immersing a finger in icy cold water and in very hot water briefly provokes a generally unpleasant sensation but it is hard to tell with the eyes closed and without prior knowledge which end of the temperature spectrum is being experienced. Pain itself the scourge of mankind (and yet his saviour in cases where it keeps him out of danger) is an incredibly mysterious phenomenon and we will not be able to say much about it here except to point out that much of its operation is determined by processes going on in the brain rather than in peripheral parts of the body. Human sensitivity to pain also varies enormously. Among certain rather neurotic people intense pain may be felt at relatively minor physical afflictions while other people may bear (or learn to bear?) what would generally be accounted as gross physical discomfort with equanimity. The action of pain-killing or analgesic drugs is also very poorly understood. Even the simple miracle of aspirin, one of the most useful drugs known to mankind works without us knowing why or how. Conversely doctors have known for centuries that some people's agonising symptoms may be relieved by the administration of a sugar pill. In a later section (Motivation) we shall try to get a little deeper into the psychological mechanisms of pain or more precisely its opposite, pleasure and will leave our investigation of the known human senses at this point with as all psychologists freely admit vast areas still awaiting exploration and delineation.

(i) Are there any Other Senses?

If we take pleasure and pain as separate senses which might seem reasonable then even forgetting about all other possible sub-divisions of sensory detection the traditional five senses are not enough. Most psychologists however are content with the traditional categorisation. One important area not particularly well covered by the present human sensory range is that of high energy radiation beyond the ultra violet. It so happens that until quite recently few living things came much into contact with radiation of this kind—the odd cosmic particles bursting through the earth's envelope of air while dangerous ones too rare to be worth developing special receptors for. Within the past century however man has begun to work regularly with high energy radiation sources and has suffered a good deal as a consequence. X rays for example were grossly misused in the early days after their discovery and similarly numerous deaths have been caused by the misapplication of nuclear fission devices. The problem is simply that although the radiation is doing our body mortal harm we expose ourselves to it because we are not equipped with radiation detectors to warn us. Once the pain arising from tissue damage arrives—it may take decades for the damage to become apparent—it is too late to do anything about the original stimulus.

This apparent digression is merely to remind one of the tremendous role the senses play in our lives and how brief our span of life in this dangerous universe would be without them. But what of other senses? A frequently used term is that of the sixth sense and many people believe that humans and animals are equipped with some other major sense which allows the creature either to detect some danger at a vast distance—way beyond the range of vision or audition—or alternatively to allow one mind to communicate with another mind. We discuss this problem briefly in the section on Ideas and Beliefs but it also has a place here since many people believe that the study of extra-sensory perception is a legitimate branch of modern psychology. The first argument against the idea of ESP (you may not feel it is particularly convincing) is that no one has been able to detect any mechanism in any part of the brain which could possibly be transmitting or receiving the messages conveyed by the sixth sense. Believers in ESP reply (a) that one might be discovered at any time and (b) that perhaps no transmitter or receiver is necessary anyhow. The first point is of course irrefutable but the second raises a different question and suggests that whatever mind to mind contact is it cannot be looked on in the way we have been attempting to look at either sensation or its necessary complement perception. There is an even more cogent argument however which the vast majority of psychologists today adopt—that there is simply no experimental evidence for the existence of telepathy anyhow. In this case it is quite unnecessary to start looking for mechanisms to mediate it. In experiments conducted to sort out the ESP controversy psychologists have found that people are very much better at gathering information from each other without the use of speech than had hitherto been realised. Tiny changes in facial expression, nervous movements, shifts of eyes even long periods of unusual silence can all serve to give the trained observer important clues as to what is going on in another person's head. Fortune tellers, detectives and expert card players have known this for years and are only too aware that they are getting their information by clever and insightful use of their normal senses but rely on other people's ignorance of just how good these mechanisms really are.

(i) Sensory Deprivation

Any individual human or animal born without a reasonably complete complement of senses would almost certainly be doomed to an early death or a life of relying on other humans for assistance. A few startling souls such as the late Helen Keller fought their way out of the solitude of total blindness and deafness to lead full and useful lives but these are golden exceptions to a fairly inflexible rule. Miss Keller in her autobiography tells of her gradually emerging realisation that the universe consisted of other things outside herself and states that it was only through an understanding of this that she began to form the concept of herself as an individual personality. This serves to reinforce the point of view stressed by modern psychology that the individual is a mesh between himself and his environment. True personality has no reality without constant and evolving interplay with the external world.

Some Experiments

In the early 1950s as scientists began to see that man would soon be able to reach the stars into space the psychologists began to ponder how well human beings could stand up to the physical and psychological isolation of a space capsule. Man is gregarious, naturally at ease among his fellows and tends to become eccentric and unbalanced when separated from other humans for any length of time. What they asked would be the effect of the extended and rather dramatic isolation imposed on the astronauts of the future? To test this a number of experiments were set up in which people were isolated in sealed chambers under conditions of greatly reduced sensory input for lengthy periods. Initial studies seemed to show that the experience was unexpectedly

unpleasant and sensing that they were on to something significant psychologists at McGill University in Montreal where the pioneering work was done decided to lighten up their experimental situation. Students were hired at the relatively princely sum (for students) of a dollar an hour and told that they could spend as many hours in isolation as they pleased. They were then placed in stuffed clothing rather like divers suits and lowered into chambers of water maintained at body temperature. The helmets of their suits were lightproof and the chamber was sealed and covered to be soundproof. The outcome of all this was that even if the student made a body movement he would feel no apparent response as his body encased in the bulky clothing would merely float around in the unresisting water. External vision and sound being eliminated and with ears plugged to prevent him hearing his own breathing the subject was in a state of almost total sensory deprivation. His only link with the outside world was a panic button which he could press to alert the experimenters if for some reason he wanted to terminate the experiment. What did the psychologists expect? That most students would like nothing better than to do nothing for weeks on end and get paid a solid wage for doing so? The results surprised everyone. Most subjects had had more than enough after only a few hours and only one stuck it out for more than a day and he suffered a neurotic breakdown. For a human being total isolation from sensory input is evidently one of the most unpleasant experiences imaginable.

The experiments caused a surge of controversy and a good deal of speculation as to what the results implied. The students' principal objection was that they became oppressed with vivid and bizarre hallucinations both visual and auditory apparently comparable in strength and unpleasantness to the hallucinations reported by alcoholics suffering from *delirium tremens* or (more fashionable today) the worst excesses of an LSD trip. These vanished as soon as the subject was removed from the chamber and apparently did not occur again. The first hypothesis advanced was interesting—that living things have a hunger or need for sensory input comparable but of greater strength to the need for food. Further more when the sensory appetite was not assuaged the brain began in desperation to create its own sensory material hence the hallucinations. This hypothesis was unchallenged at first but an alternative point of view has recently been put forward based on the recent discoveries in the field of sleep and dream research (see P56-52). Many psychologists now believe that humans need to dream and that one of the principal functions of sleep is to allow our brains to undergo a kind of sort out of the programmes which control the central computer. In this view the hallucinations occurring during sensory deprivation would really be an example of the individual dreaming while he was awake the subject's brain having been fooled into thinking that it was asleep by the sharp reduction in sensory input which had occurred. For various reasons the human brain carefully keeps the important process of dreaming separate from the waking state and there is some suggestion that to fully experience our dreams would be a psychologically intolerable experience. If this is correct then the McGill experiments and their successors show not a need for sensory input with consequent hallucinations to feed the sensory appetite but rather the effects of allowing waking human beings a glimpse of the inner space of their minds. Similarly incidentally one can look upon both the LSD trip and the alcoholic hallucinations as examples of the same process occurring—except that the tripper has stimulated his dreaming mechanism into action through the drug while in the case of the alcoholic his excessive intake of alcohol has led to an inhibition of the normal dream process which bursts into activity when he is awake. Whatever the explanation for the strange experiences of the isolated students there is no doubt that the human being is not psychologically equipped to face up to total loss of sensory inflow for any sustained period. The adventures of the astronaut have in fact taken place in relatively richly-endowed sensory environments and so the

expected problems have not arisen. But what of space voyages lasting for months or even years?

(k) The Problem of Attention

We have now really finished with the sense and perception as such but before moving on to our section on Learning and Information storage we need to think a little bit about the problems which are posed by the great influx of information to the brain how it sets about coping with this and how it assigns priorities to the multitude of signals it is faced with. This involves the process which we know as Attention. To get some idea of the task facing the brain let us take up another simple analogy even if it isn't 100 per cent accurate to the purist's eye.

The brain can be likened to a complex communications centre sorting vital information rather like an air traffic control at an international airport. Information floods in from various sources with the controller paying attention to the scene through the windows to radio calls to messages coming by teleprinter and by hand etc. One way to sort out the muddle might be to assign one mode of messages to one controller the second to another etc. but the problem of co-ordination remains. At some stage the senior controller must select which set of signals he is to work on switching when appropriate to other sets and issuing instructions to the aircraft waiting to take off and land. Now there are two ways in which he might select the information. The first would be to cut off the unwanted signals at his desk by refusing to allow the stimuli to reach him a strategy which might lead to a jam of information such as messengers bits of paper telephones off the hook etc. cluttering up the control room. A second strategy would be to staunch the flow of information in the unwanted channels closer to their source in this case at the point where they first come into the control tower. Real air traffic centres fortunately never get into the kind of muddle we are implying here and nor in most cases does the brain. But which of the above strategies is the closest to that adopted by the brain in attending to one particular set out of a vast pool of competitive information? Until about 10 years ago psychologists tended to favour the idea that the first of the two systems was in operation with every sensory stimulus making its way to the brain to contribute to some great tangle in need of constant sorting out. Confusion and uncertainty under stress were considered to be an example of the tangle getting momentarily too complicated.

The Work of Hernandez Peon

This view has now been largely rejected thanks to some brilliant experiments by the outstanding young Mexican psychologist Raul Hernandez Peon, who was recently tragically killed in a car crash. Hernandez Peon's experiment which many people consider to be the first big break through in the psychological study of attention was performed first on that most useful of laboratory animals the cat, but later repeated on other creatures. The first stage was to implant a microelectrode into the cat's brain, specifically in an area known as the cochlear nucleus. You will recall the word cochlea from our section on audition as being the seat of the translation of the incoming sound waves into electrical signals. Now the cochlear nucleus is the first major junction box at which auditory signals meet before beginning their ascent to the brain. Prior to this there is only the network of neurones springing directly from the tiny hairs in the cochlea itself. By attaching the electrode to an amplifier and looking at the output on a TV screen, the experimenter could watch the electrical impulses from the ear as they passed through the big nucleus. The ticking of a metronome for example could be seen as a regular beat in time with the tick. Hernandez Peon then set about trying to attract the cat's attention away from the metronome and did so by showing it a mouse. The cat as predicted gazed interestingly at the mouse where upon—the electrical signal indicating the still ticking metronome vanished from the TV screen! This is odder than one thinks at first. Remember

that the electrode was planted in the nucleus in the region of the ear and yet the electrical signals were no longer passing this point. If the metro home was still ticking then its sound waves should still be activating the ear and should still be trying to send their impulses up the auditory nerve. Clearly then a gate was being closed not in the brain but right down at the level of the ear—the message to close it however presumably being sent down from the brain. How could this gate shutting message get down to the ear? Evidently there must be neural fibres which send their messages downwards from brain to receptor and not just in the other direction as had hitherto been believed. These corticofugal fibres as they are called are now believed to run to other sensory areas including to the retina in animals and humans, and while they are very difficult to track down by anatomical analysis they are thought to serve a very important function. The facts of the case seem to be that Hernandez Peon had discovered one of the basic mechanisms of attention the ability of a creature to filter relevant from irrelevant information. Thanks to his work it now looks as though the brain prevents itself from having to face a muddle of conflicting information by cutting off the unwanted signals actually at the level of the receptor thus preventing a press of confusing and irrelevant information from flooding in. Once attention shifts again then the appropriate gates are opened and information flows as before. If this tells us something about the selective filtering of important as against useless information does it also say something about the way a mother will be undisturbed in the night by the flight of a jet plane and yet wake to her child's slightest cry? Perhaps this is an area which mothers know more about than psychologists ever will.

III LEARNING AND MEMORY

(a) How is the Information Stored?

Earlier we discussed the specialist use of the word information that psychologists and other scientists employ and remarked how important it is for an understanding of current work on the brain that one rid oneself of the idea that information can only be conveyed in the form of spoken or written messages. We now need to consider the general problem of the storage of information, a concept fundamental to the interesting topics of learning and memory. Most people can readily accept the idea that a book is a store of verbal information as in a different way is a gramophone record. In reality in neither case are words actually stored. In books the information is held in the form of coded marks called printing which need to be decoded by the reader before he can understand the original message. Similarly in the case of the gramophone record the information which might be the sound of a pop star singing is coded into the form of a series of ridges on a plastic the decoding being done by a needle plus amplifying equipment speakers etc. Using devices like books films and records information can be held in store for very considerable periods of time the original message sitting around more or less indefinitely until someone gets down to decoding it. Messages written on the walls of prehistoric caves by our dim and distant ancestors are still passing their information across today and even the fossils we find in Cambrian rock formations are messages of a kind, though the senders did not consciously originate the signals. In essence then a message consists of an information source some kind of transmitting medium and a receiver. There may also be a delay built in—storage—in which case some kind of encoding and decoding process will be added to get the message in and out of store. All this preamble leads us now to the point where having in the previous section considered the information gathering and decoding processes in the brain, we can now consider its role as a storage device. Unlike books and records which operate on fairly simple lines the brain chooses immensely complicated and still rather mysterious techniques to do its job.

First, perhaps we should clear up a small point which otherwise will cause confusion—the fact

that psychologists distinguish clearly between the two processes learning and memory. In fact the distinction is simple particularly in the light of the principles we have just been considering. Learning is the process of feeding information into store and memory (or remembering) the process of extracting it once again. The next question is the really big one—in the case of the brain just how is this done?

Returning momentarily to gramophone records and books we can see that the process of information storage implies that the incoming signal has changed the state of the storage device book record or whatever in some way either by covering it with marks ridges or in the case of magnetic tape altering the electrical properties of its surface. Something similar must happen in the brain. Information flows up from the receptors is processed or interpreted by the perceptual mechanism and then depending upon circumstances fed into some store where it is held until required. What kind of changes could be taking place in the neural circuitry of the brain to constitute the laying down of a memory? Psychologists have been divided on this question for decades and there are three fairly separate competitive approaches. Without giving too much away we shall probably end up feeling that the true explanation will turn out to be some kind of mixture of all three. The three main suggestions can be summarised as (1) the neurological (2) the biochemical and (3) the electrical.

The first suggests that as information is fed in, causing certain patterns of brain cells to be activated, minor changes take place on the structure of these cells modifying them in a rather gross physical way. This would be similar in a sense to the changes that take place in the surface of a gramophone record when it is first made. The second argues that such gross changes are unlikely and that the storage must take the form of modification of the biochemical or even molecular structure of the brain changes taking place within rather than on the surface of individual cells. The third view advances the hypothesis that since the brain is a mass of electrical energy and electricity is the basis of neural activity then the psychologist should look for changes in the electrical patterns of the brain as an index of the fact that something has been stored. We will look at each point of view in greater detail shortly but first it will be useful to study the experimental evidence.

(b) Early Studies of Learning

Experimental psychology started in the latter part of the 19th cent largely as the result of pioneering work of the German physiologist and psychologist Wilhelm Wundt. No one today gets greatly excited at Wundt's experiments nor at his writings but he was one of the first people in the world to realise that one could actually subject the raw material of mental activity to the experimental method and in this way he is memorable. Wundt concentrated on perception and similar topics and also conducted the first studies of reaction time—the delays humans make between being given the signal to start a task and actually beginning it. He had little to say about the matter of learning and memory leaving it to a successor Hermann Ebbinghaus to get the ball rolling in this area.

Ebbinghaus's experiments were beautifully simple. He took human beings into his laboratory and set out to teach them lists of words plotting the success rate (number of words in a sequence remembered) against the number of repetitions that had been given. This may all seem frightfully obvious particularly when we say that Ebbinghaus found that the more repetitions the better the list of words were learned. This is exactly what one would expect now a century later but at that time things weren't so clear cut. Furthermore, Ebbinghaus showed that when you plotted the rate of learning on a graph, a very characteristic curve emerged common to all his normal subjects, which indicated a gentle improvement in learning with the first few repetitions of the list, followed in due course by a sharply accelerating rise which in turn tapered off. Finally a point came when the list was either

completely learned or no further improvement was made. The important factor was that while there were individual differences in the final level of achievement and also in the time taken before the main surge of learning took place, the shape of the curve was very similar for all subjects. In other words while there were significant differences in the ability of subjects to learn his words the nature of the learning process seemed to be interestingly similar. Ebbinghaus's findings are as valid today as they were then and his learning curve fits rather well to the overall pattern of animal learning as well.

In his quest for objectivity he produced another interesting idea. It seemed to him that if one were to compare the performance of two different people in a learning task one couldn't deduce much about their respective talents by examining the slope of the learning curve unless one knew something about their previous experience with the subject matter. For example one person might because of his job or something simply have been more frequently exposed to the material featured and this would give him a built-in advantage which confused the issue. How about using foreign languages? Again Ebbinghaus felt that to get absolutely pure learning curves one would have to be certain that the subjects had not received prior exposure to the languages in question—a task almost impossible in principle. This led to his invention of a curious tool in the psychologist's workshop, the nonsense syllable which is still used today as the standard material for many tests of learning ability. It consists of a word with a meaningful sound and look to it but which is almost complete nonsense inasmuch as it has no obvious meaningful association. ZAT BOK FID BLJ HAB are a few examples of this strange vocabulary. Ebbinghaus type experiments are as you can believe immensely boring to perform and subjects today normally have to be paid in order to persuade them to take part! However his realisation that human learning processes could be brought into a real if rather dull laboratory setting was a big step forward. Furthermore he had realised the necessity of separating out performance in one task from the background of past experience, an idea which has had far reaching consequences on the design of all psychological experiments since and which even touches on the important question of the interplay between heredity and environment which we shall look at in the final section.

(c) Learning Experiments with Animals.

The use of nonsense syllables gets over the problem of past experience in one limited area of experimental psychology only and if one really wants to know something about the formation of the learning process from scratch then one either has to start with very young babies or use laboratory animals. One psychologist went so far as to read aloud lengthy passages of Greek prose to his infant son at an age when the baby couldn't even understand English. Years later the psychologist gave his son by now a young man, a number of passages of Greek prose to learn, among which were the sections the baby had previously heard. The outcome was that the sections to which the child had been exposed as a baby were found to be significantly easier than the fresh material. This odd and very tedious experiment has never been repeated though it is generally rejected by psychologists today as having been imperfectly controlled. For example who can say for certain what the young man had or had not learnt in the period between the two phases of the experiment? It nevertheless remains as one of a few heroic efforts to use young babies as subjects in learning experiments and it also highlights some of the great difficulties involved.

By the turn of the century more and more psychologists were beginning to follow the lead given by their physiological cousins in bringing animals into the research laboratory. One of the first and most important figures to do so was the American Edward Thorndike, who began to look at the behaviour of specially bred white rats in laboratory learning experiments. Now with humans the problem of how to get the subject to

do what one wants him to—learn nonsense syllables or whatever—is met by simply speaking to him about it. With animals this won't work so Thorndike decided that they would have to be rewarded in some way if they were to learn anything. Reward can be any one of a lot of things and for an animal it can be getting out of a situation it doesn't like such as some kind of maze or puzzle box in which a number of specific moves have to be made in sequence before it can get out. Thorndike found that most animals make strenuous and fairly determined efforts to get out of boxes mazes etc and can follow a fairly elaborate sequence of moves in order to reach their goal. Rats for example will learn to press a series of levers in the right order if they will open the door to a box and they will gradually get better and better with practice. Similarly when placed in a complicated maze provided they are rewarded with food or escape at the end they will soon find their way round it. The crucial point here seemed to be the reward and while pet owners have known for centuries that a piece of sugar presented at the proper time will make a pet do tricks it is really not clear why it should. To say that it is because the animal wants the sugar is no explanation as to why this trick should be learnt rather than some other pattern of behaviour. But Thorndike found without doubt that an animal would learn a maze or similar task far better if it were rewarded in some way at the completion of the task and he too couldn't see just why in physiological terms the neural events which made up the correct performance of the task should be built in simply because the animal was rewarded while incorrect patterns of behaviour were rejected. Ebbinghaus had come to the conclusion that successful learning was a function of the number of times the task was repeated. Thorndike argued that while practice helped to make perfect it needed something else as well—the successful completion of the act. How would one measure success? Well getting out of a maze or finding sugar at the other end would presumably count and Thorndike described this principle as the Law of Effect believing that he had discovered two factors necessary for learning to be successful (for the information to be placed into the store) one being frequency the other being effect. Psychologists at the time carefully sidestepped the nagging question of how effect (something happening at the end of a sequence) could work back in time to establish the sequence in memory by assuming that the reward or reinforcement did not itself cause the sequence to be stored in the memory system. It simply made that sequence more likely to be called up on some future occasion. But replied the critics, wouldn't that imply that all sequences were stored with both right and wrong behaviour lodged equally firmly in memory? This question is still being hotly debated today and we will shortly be taking a look at the evidence concerning what is and isn't learnt in an experimental situation. But first a word about one of the most important concepts not only in modern psychology but also in 20th century science—the conditioned reflex.

(d) Pavlov and the Conditioned Reflex.

The great Russian physiologist Pavlov reached the peak of his scientific genius in the early years following the Communist revolution in Russia where his very physical approach to psychological phenomena found favour with his country's leaders. The reasons were ideological. To many it seemed that Pavlov could explain all behaviour in purely mechanistic terms and thus do away with mystical, metaphysical and to Communist thinking, totally out-of-date views of Man's nature. Pavlov it was felt, was at last exorcising the Ghost out of the Machine. His findings in fact sent ripples across the world and the face of psychology was changed by them—notably in injecting into it the realisation that a good psychologist must think like a physiologist at least as often as he thinks like a philosopher. On the other hand his naively simple view of the machinery of mind and brain was bound sooner or later to be exposed as only partially adequate

missing many of the richly complicated facets of human behaviour which must be faced up to and not denied. What was Pavlov really saying? At rock bottom his ideas revolved around the notion of the conditioned reflex arc a concept that all wishing to understand modern psychology must get clear in their minds sooner or later.

The experiments in question were exceedingly simple inasmuch as they confined an animal to a rather limited environment and studied its behaviour in the most fundamental kind of learning situation. Pavlov who was enormously interested in gastric and salivary secretion had noticed that some of the animals in his laboratory would respond to the presence of food with copious flows of saliva, while others would not. Some would even respond excitedly when a particular food pan appeared while others again would not. He reasoned that these differences were in some way a function of the particular animal's past experience and set out to study this in detail. Firstly he devised a method of measuring saliva flow which would normally be copious when an animal was presented with its food and reflex arc intact. He duced just prior to the presentation of the food, a buzzer, bell, light, or some other similar stimulus. Initially the preliminary stimulus would yield no salivary response but after a while provided that the pairing of the presentations was kept up the first traces of saliva would begin to appear upon the sound of the bell. If this were reliably followed by food soon the saliva would appear in full flood to bell alone. Failure to offer up the food however if persistent would lead to a gradual falling off in the amount of saliva until it ultimately dwindled away. Pavlov declared that this must imply that a probably instinctive reflex—salivating to food—had become linked in neural terms with a stimulus which had at first been totally irrelevant, the sounding of a bell. The more frequently the two events were linked and the more closely they were associated in time the stronger the new reflex arc would be. Lack of association between bell and food would lead to the extinction of the reflex arc. The fact that extinction was not total could be nicely shown by introducing the food again whereupon things would come rapidly back to normal with the bell producing copious flows of saliva once more. Today this seems a fairly trivial observation but at the time Pavlov his co-workers and psychologists all over the world became immensely excited about the conditioned reflex. The reason was that there seemed to be no reason in principle why the whole of an animal's behavioural responses had not been acquired in just this simple way with the same argument applying with equal force to humans. At the root of all behaviour lay a simple physiological principle. By employing this properly all living things could have their behaviour patterns moulded in whatever direction was felt to be appropriate. All psychological malfunctions could be corrected, education made simple, the wild beast tamed, the workings of the brain fully described and comprehended. This for a brief period was the golden goal (if one likes to think of it in that way) of the new science of psychology—to see man for what he really was, a complex mass of inherited and conditioned reflex arcs.

If Pavlov and his followers in Russia clung to this dream for decades longer than did less politically committed scientists in other parts of the world then this is understandable. One of the goals of scientific endeavour is simplification and an explanation of human behaviour in terms of stimulus-response units would certainly meet part of that goal. But on the other hand part of the goal of science is also objectivity—even at the risk of complicating explanations—and before long it became obvious that the animal in the experimental Pavlovian set up was not behaving as a complicated automaton. For example it is possible to condition an animal to lift its foot to avoid an electric shock if a bell reliably signals the imminence of the shock. Now place the animal on its side, ring the bell and—will the animal lift its foot? Yes—but not before getting up to the standing position first. But if the animal is blindly responding to the ringing of a neuro-muscular reflex arc why does it not simply raise its foot while lying down? And how does the standing up act become incorporated into the

reflex sequence without prior training? Such experiments were simply discounted at first as being too inconvenient for the theory but as time went on the immense oversimplification of the stimulus-response theory of behaviour became obvious. But not before a major movement sprang up in the United States which attempted to make dynamic and imaginative use of Pavlov's findings in an attempt at an all embracing psychological theory. We now turn to look at this the so called Behaviourist School.

(e) The Rise of Behaviourism

Sometime before Pavlov's ideas began to have impact in the West a spontaneous movement had been developing among psychologists to reject the traditional methods of introspection in experimental research. The interplay of conscious thought and mental activity was felt inevitably to confuse the issue and workers were urged wherever possible to make objective rather than subjective judgments. One of the hardest advocates of this line was J. B. Watson who even went so far as to argue that introspective studies of consciousness etc. were not merely misleading but positively useless. In principle Watson proposed it should be possible to give a total explanation of the subject matter of psychology—whether human or animal—in descriptive mechanical terms concerning the outward manifestations of behaviour. This implied ultimately taking such extreme points of view as declaring thinking to be merely sub-verbal speaking better described in terms of minor twitches of the throat, mouth and tongue muscles than in patterns of electrical activity in the higher centres of the brain. All that was needed to give the Behaviourist school impetus was Pavlov's discovery of the conditioned reflex and when this was published it was eagerly incorporated as the prop of Watson's argument. To Watson and his colleagues the only realistic and profitable way to look at human and animal behaviour was in terms of a strictly mechanistic model, the conditioned reflex arcs serving as the vital links in the creature's chain of activity. Now many people might agree that an animal in a highly restricted laboratory situation trained to salivate to bells, raise its paw to avoid an electric shock etc. might well be coming as close to a biological machine as one could imagine but was this a really adequate way of describing its behaviour in the wild? Critics of Behaviourism were quick to point out certain peculiarities that they felt could not be handled by Watson's simple system. Take a dog for example and face it with a series of doors behind one of which is to be found food, sometimes one door some times another. Now train the dog to respond to a light switched on briefly as signalling food. Now indicate the door which has food by switching on a light above it and the dog will soon learn to trot up reliably to the appropriate door. What has happened? Easy say the Behaviourists—the dog has been conditioned to approach a light for food and the reflex carries over to a light above a door. The dog is not really responding to the door but to the light which sets the appropriate reflex arc in motion just as pushing a button can cause a car to start. But what the critics argued, about the fact that the light is switched on for only a few seconds and yet even after it is off the dog still moves towards the door? Watson replied that the light caused the animal to look towards the door and it immediately adopted a particular posture setting its musculature up so that it would set off in the appropriate direction, no longer needing the light for a guide. This might seem fair enough, but for the fact that if just as the animal is about to set off for the door you hold it refusing to allow it to move it still shows interest in the door. Furthermore if you let go in five minutes time the chances are that the animal will set off to the correct door—a bit long one would have thought for the reflex arc to have been maintained in suspended animation. Was it not simpler Watson's critics replied to face up to the fact that the animal was using the light as a signal and was holding the door in some mental form as a kind of goal to which it could make a delayed response if necessary? So adamant were the Behaviourists that all behaviour

could be explained in terms of sequences of conditioned muscular movements that they strove to argue that even during the delay the animal was still maintaining a muscular posture—rather in the way that a hunting dog freezes to point to prey. Furthermore, Watson produced what he believed to be irrefutable evidence for the dominance of the muscular activity even on a task as complex as learning to run a maze. In this rather cruel-sounding experiment he trained a whole lot of rats to find their way through a rather detailed maze. He then proceeded to eliminate by surgery all normal sensory equipment—eyes ears smell etc leaving only the kinaesthetic or touch sense. These grossly deprived animals nevertheless still managed to find their way through the maze allowing him to conclude that in line with the conditioned reflex notion the animals were relying predominantly on a chain of muscle reflexes. For a brief period this dramatic experiment seemed to clinch the Behaviourist case. But then came a counter experiment even more drastic. A psychologist called Lashley repeated Watson's experiment but this time also removed the sense of touch by spinal surgery. The wretched creatures even now managed to stagger through the maze—though they were certainly no longer equipped with proper muscular responses. Lashley correctly felt this dealt with the ultra-simple Behaviourist argument and that somehow or other the animals must be retaining some kind of general, predominantly sense sort of notion as to where the exit lay. At about this time more attacks on Behaviourism came from a rival point of view—the Gestalt school. Watson himself shortly afterwards became involved in a sensational divorce case which forced him in those less permissive times to resign from academic life. He ended his brilliant career in of all things the advertising profession.

(f) Gestalt Psychologists and Learning

With its emphasis on such ideas as the whole is something more than the sum of its parts and its insistence on the idea that the brain has dynamic organising powers which serve to modify input and intervene between stimulus and response the Gestalt point of view was clearly about as far removed from the naive Behaviourist view point as was possible. One of the principal allies of the Gestaltists in its early days was K. S. Lashley referred to above a brilliant experimentalist with an eye for the essentials of the problem. Throughout his long research life he remained open minded about various schools of psychology and unconvinced on the various rival theories concerning the physiological basis of memory. He was however quick to see the basic weaknesses in the various brain models that fellow psychologists were always confidently erecting and the first to feel the sharpness of his attack were the Behaviourists. Lashley swiftly realised that the attractive simplicity of the Pavlov/Watson argument was that the basic unit in learning consisted of a fundamentally simple physiological system a neural reflex arc. In ordinary terms this could be looked on as a chain of cells connected from say the retina through the higher centres of the brain (where the chain would be forged) down to the muscle or set of muscles which constituted motor output. In other words a light would strike the retina, a number of cells would fire. These in turn would excite cortical cells which had by prior conditioning become linked into a reflex arc. Finally these would quite mechanically induce the appropriate muscular response. The memory it self constituted the connecting cells in the cortex and this memory had been established by the learning or conditioning process. Lashley then realised that a memory unit or an engram as he named it must be represented by a particular set of cells in a particular part of the brain. In principle therefore one should be able to discover these sets of cells and find out what kind of memory is located in what part of the brain.

Lashley's technique was again that of surgical destruction of tissue and using this he performed one of the most remarkable experiments in the history of modern psychology and physiology. His findings created a shock of disbelief and con-

troversy and their full implications are still not fully understood today—about 50 years after he performed the experiment. Taking a large number of rats he trained them until they were highly familiar with a complicated maze. He then proceeded to remove from each rat a small portion of cortical tissue taking a different area but an equivalent amount from each rat. In due course he had removed from his collection of rats the equivalent of one complete brain though no individual animal had had more than 5 per cent of its cortical tissue destroyed. He then took another set of rats trained them in the maze and again removed the equivalent of a brain but this time taking 10 per cent from each rat. With a further sample he went through the procedure again but removed a quarter of each rat's brain and in his final group he had a limited number of animals each of which had half its cortex removed. See if you can guess what he found. Remember that if the memory or engram consisted of a series of linked cells then one might expect that these would be found in one relatively small segment of the brain. Interrupting the chain at any point should presumably destroy or grossly handicap memory. Now from the simple Behaviourist point of view most people would have to predict that one or two rats whose hunk of cortex removed had featured the conditioned reflexes involving the maze would be completely clueless when placed in it. The engram would have been removed. This would then tell the experimenter as Lashley had hoped which part of the brain dealt with such tasks as maze learning. Other animals who had not lost their maze engram would show no detriment in their performance of this task. To his amazement and to everyone else's for that matter Lashley found that his first group of rats, each of whom had lost about 5 per cent of cortical tissue were apparently totally unaffected by the surgery running the maze just as well as they did before! The rat with bigger chunks of tissue removed were slightly more affected but even those with only half a brain left were still able to run the maze fairly competently. The loss of memory seemed to be somewhat proportional to the amount of tissue removed but *not in any way to the area removed!* In other words the mysterious engram did not seem to be located in any single spot and Lashley was forced to conclude that it looked as though learning and memory were a function of the whole brain rather than just part of it.

As could be imagined these findings were not well received by the conditioned reflex advocates and numerous attempts made to repeat them merely served to support these first findings. They were received enthusiastically by the Gestalt psychologists who saw them as another example of their argument that the brain must be considered as an integrated whole and not as simply a bundle of conditioned reflexes.

The next strong—perhaps the strongest—anti Behaviourist argument came from one of the Gestalt school founders, Wolfgang Kohler. His findings were disclosed in his important book *The Mentality of Apes* which can be bought in paperback and which everyone interested in psychology should read. Kohler who was one of those clever scientists who manage to find themselves work in exotic parts of the world conducted his critical experiments at the Primate Research Station in the Canary Islands. Here he watched with great interest the considerable learning skills of the higher apes such as chimpanzees and quickly arrived at the conclusion that conditioned reflex theory was not adequate to explain the scope of their intellectual behaviour. His most famous observation concerned the never-to-be-forgotten chimpanzee Sultan. Kohler had noticed that chimpanzees will play about with sticks and similar devices in their cage which they seem to use as toys. He then began to wonder whether the monkeys could ever be induced to use them as tools so after placing potential implements inside Sultan's cage he then put a banana on the other side of the bars just outside its reach. After a bit of fruitless stretching the ape took one of the sticks and pulled the banana in. Now this in itself is a remarkable achievement and if the ape had actually "worked out" the solution then it would have been suggestive of very much higher thought processes in the

animal than had hitherto been believed possible. However it could be reasonably argued that the chimpanzee had seen some other person or animal using the stick as a tool and was therefore merely imitating an action which could with a bit of latitude be thought of in behaviouristic terms. Kohler's next step put paid to that point of view. He placed in the cage several sticks of various lengths which could be fitted together to form a longer one and taking care not to show this technique to the monkey again set a banana outside the bars but out of reach of any one single stick. After scratching round fruitlessly with various sticks and making aggrieved noises Sultan began to play rather aimlessly with the sticks occasionally fitting them together by chance. Suddenly Kohler who was watching saw the chimpanzee fit two sticks together stare at them for a moment and then as if making a decision walk rapidly to the side of the cage and with this new long pole pull the banana in. The moment of comprehension when the ape realised what he could do Kohler wittily termed the 'ah ha' reflex, a phrase which sums up beautifully a sensation we all understand and which was totally unaccounted for by the Pavlovian approach to the problem.

(g) Later Developments in Learning Theory

You may have the feeling that Behaviourism conditioned reflex theory and its attendant experimental studies are more or less worthless and a hindrance rather than a help to the development of modern psychology. This is far from the truth. The point is that despite its vigorous self-confidence and contempt for introspective approaches to psychology Behaviourism really only falls down through its pretensions to providing a complete theory of mind and brain. The Behaviourist experiments still work and there is undoubtedly much to be learned from the conditioned reflex though one has next to no idea from the physiological point of view how it is laid down. Throughout the 1930s and beyond psychologists supporting the Behaviourist position performed thousands of ingenious and often highly imaginative experiments to back up their ideas these always being subject to counter attack from the opposition most of whom were followers of the Gestalt school. For years arguments raged over Kohler's insight study with the chimpanzees and became even hotter when experiments claiming to demonstrate insight in lesser creatures such as rats were performed. Gradually under intense pressure the Behaviourist hard line softened the pretence that animals were no more than bundles of totally automatic reflexes was quietly abandoned. Once this occurred and the Behaviourist method was put to work studying the functioning of living systems then experimental psychology was set for a boom. One of the most significant features of the conditioned reflex method as exemplified by Pavlov's original experiments was its usefulness for examining the nature of animal perception. Offhand one might wonder how it could be possible to tell what an animal sees or more exactly how fine is its capacity for perceptual discrimination. How could one find out whether a rat could tell the difference between a triangle and a square and between one colour and another? One can ask humans but rats? In the case of colours what one could do would be to train the creature to respond to a red light and then gradually alter its hue in the direction of another colour say blue. If before one had made much of a change in hue the animal was ceasing to respond then one would know that it was detecting the change of hue. As for shape perception the problem is even easier. In the very early days Pavlov conditioned his dogs to respond positively (i.e. with saliva) to a circle, and negatively (i.e. raising paw to avoid shock) when a rather angular ellipse was shown to it. Then he gradually made the circle more and more like an ellipse and the ellipse more and more like a circle. Up to a point he got clear-cut appropriate responses, until the pattern lay somewhere in between. At this point the dog, poor creature, had a nervous breakdown, which wasn't too nice for it but which told Pavlov a lot about its sensory and perceptual

processes. While on these slightly macabre topics it might be worth mentioning that today dogs and rats have largely been supplanted for behaviouristic studies by a rather quaint choice of animal—the pigeon. The fact is that pigeons have been found to have quite remarkable powers of sensory discrimination and will peck away at buttons to get food or avoid electric shocks for hours on end. So good is the pigeon at telling the difference between patterns that it was even once proposed for a fantastic rôle in modern warfare—not its traditional job of carrying messages from spies but believe it or not as the control centre for a flying bomb! In the early days of guided missiles the kind of electrical equipment available was too bulky cumbersome and unreliable to be easily put into flying bombs. This was particularly true about the equipment necessary to allow the bomb to select the correct target at the other end. One bright psychologist argued that the pigeon would be an inexpensive compact and reliable pilot for a flying bomb. The device could be trained with pigeon in a little cabin could be launched off on course and when the bird spotted the target (say an enemy battleship) which it had been previously trained to recognise it would peck at the appropriate button and that would be that! So far as one can tell the idea was never implemented which is probably a good thing for us humans—to say nothing of the pigeons. The idea might be described as one of the less fruitful to come from Pavlov's original idea and serves to remind us that psychology just as any other science can be properly or improperly used depending upon circumstances and the individuals involved. But let us now return to the basic question—what is the actual nature of the learning process or the memory trace?

(h) The Nature of the Engram

Earlier we said that there were three broad approaches to the problem—the memory trace the neurological the electrical and the biochemical.

(1) The Neurological

This is probably the kind of model that Pavlov would put forward today if he were alive. To understand it remember that the conditioned reflex is essentially a chain of cells running from sense organ to motor output (finger, paw, eye, blink whatever). The cells of course were there in the first place built into the animal from birth. It is the connections between cells, the links in the chain that are forged in the learning process. Fine but how are the connections formed? Why one chain rather than another? A number of attempts have been made to solve this one, perhaps the most ingenious in recent years coming from the Canadian psychologist D. O. Hebb an architect incidentally of the sensory deprivation experiments and one of the first psychologists to be elected as a Fellow of the Royal Society. Hebb had been impressed by the discovery that nerve cells were frequently adorned with tiny bumps or knobs which tended to cluster at the points where the cell made contact with other cells—the *synapses*. There was even some suggestion from microscopic studies that these synaptic knobs tended to become larger and more profuse in the brains of more mature animals. Suppose Hebb argued that when a nerve cell was fired, it made contact with another via a synaptic knob and thus triggered the second cell into action. Suppose also that each time a synapse was bridged via a contact knob this knob grew a little as though through exercise and thus made better contact. This, as time went on, would significantly raise the likelihood of a nervous impulse crossing at this point. If one can imagine the process repeated with a whole series of cells then one can see that repeated firings would also increase the likelihood of particular chains of cells being activated thus weaving a kind of path through the nervous system down which the neural impulse would prefer to travel. This Hebb suggested could be the basis of the conditioned reflex—simply a con-

nection made progressively easier each time the route was travelled.

Hebb's theory attracted a good deal of attention when it was first published over 20 years ago first because it seemed to fit the known physiological facts (such as they were) and second because it seemed to get over one of the awful difficulties facing any neurological theory of learning—the experiments of Lashley. Recapping briefly these showed that the memory trace or engram for a particular task was not located in any one small section of the brain. Now Hebb's synaptic knob model implied that the initial path followed by a nervous impulse might be pretty random throughout the cortex wandering here and there until with repeated firings it became established. This would quite possibly be a rather strange chum and not necessarily the shortest distance between two points. Add to this the fact that the acquisition of a complex habit such as learning a maze would obviously depend upon thousands possibly hundreds of thousands of these neural links being established and one can begin to see that Lashley's experimental results no longer seem to fly in the face of reason. Removal of any single chunk of cortical tissue would simply serve to remove a more or less random selection of the neural chains serving as the maze memory. The more one took out the worse the memory of the maze would be. That single piece removed would ever eliminate the whole of the memory! To many people Hebb's theory crude though it might be fairly tackles the apparent paradox of Lashley's results. Others are not so sure. Its main defect the intervening years have shown is that his nice ideas about the growth of synaptic knobs and their significance as contact points between cells are probably no longer valid. Today their function and even their existence in the form that Hebb discussed is questioned by many physiologists. Furthermore for various reasons there has been a strong shift towards the point of view that whatever form the learning process takes it is unlikely to involve changes in neural tissue—at least of such magnitude. To many psychologists and their colleagues changes in the molecular structure of the cell must be involved. Before considering the evidence for this hypothesis we need to examine briefly the Gestalt psychologists' attempt to account for learning and memory.

(2) Electrical Field Theory

We have been talking of the Gestalt psychologists without pointing out an interesting fact—that the two principal founders were first trained as physicists! Jumping the broad gap between physics and psychology might seem a bit much, but Wolfgang Kohler was one who did it and in doing so he injected into his theorising some of the ideas basic to his native topic. In the main this involved the concepts of electrical field theory. Without going into this in boring detail, it so happens that an electrical source either in the form of a battery a current flowing down a wire or whatever spouts electrons in its immediate neighbourhood and these constitute an electro-magnetic field. As the name implies the most striking example of such a field is to be seen in the ordinary common-or-garden magnet and the structure of the field can be observed by placing the magnet in a large mass of iron filings. Now Kohler and his friends argued that the brain was a potent source of electromagnetic energy and ought therefore to create a field within and around its tissue. The field would be powerful enough to modify incoming electrical input from the senses and to some extent impose its own pattern on it. Hence the Gestalt laws of perceptual organisation. This would be a two-way process however for sensory input no matter how feeble, would impose at least minor changes on the structure of the cerebral field. Such changes the Gestaltists argued would constitute the basis of learning. It was a bold if somewhat implausible point of view and was treated as a serious alternative to the Pavlovian conditioned reflex ideas for at least a period. It had one or two gross defects however which even the Gestalt psychologists found worrying. In the

first place no kind of recording device seemed able to pick up any signs of permanent or semi-permanent electrical fields surrounding the brain. The EEG seemed to be a rhythmic picture of electrical change within rather than of a static powerful field highly resistant to change. Secondly there is the odd data from electro-shock therapy. This much maligned method of treating highly depressed psychiatric patients relies on jolting the brain with a powerful electric shock a not particularly pleasant process which nevertheless generally brings a notable remission in patients' symptoms. The point here is not to argue the pros and cons of ECT as it is called but to indicate that such tremendous shocks should be enough to seriously disturb any electrical fields no matter how well established with presumably drastic effects on memory. In fact long term memory is totally unaffected by ECT though as the Gestalt supporters were quick to point out there is short term amnesia for even a few minutes preceding the electric shock. Thirdly and finally as it happens there is the clinching experimental work of Lashley—not his tissue removal experiment but yet another in the catalogue of his remarkable repertoire. Lashley's procedure was as follows. He first taught a large number of rats a particular maze. Then he inserted in their cortex very fine sheets of gold leaf—a notorious destroyer of electrical fields. He then ran the rats through the same maze again and found no evidence of any detriment to their performance. He also taught other rats the maze after they had had the gold leaf implanted and found that they learnt it with no undue difficulty. After this work the Gestalt battle cry never seemed so loud or so convincing again. It is doubtful actually whether they ever really believed the electrical field theory but it was a nice idea while it lasted.

(3) The Biochemical Argument Some Fresh Surprises

The memory capacity of the human brain is absolutely enormous. It has been calculated that it is quite capable of storing all the information ever fed into it—in other words there is no need for anything ever to be thrown out of store to make room for fresh material. The real problem in this case is not finding enough room to pump in information but in finding a sufficiently efficient system to pull it out rapidly. Not only do psychologists believe that the brain has this almost limitless storage capacity but they also have some evidence that all the information fed in no matter how trivial actually is stored! Some of the most exciting evidence to back up this belief has come from studies made during human brain surgery. These studies are a trifle gruesome and the squeamish might like to jump a paragraph or two here.

For a particular type of surgery—such as the excision of a brain tumour—it is necessary to remove a portion of the cranium and for various reasons it is advisable to perform the entire operation with the patient fully conscious. This is not so horrific as all that for the brain itself has no pain detecting cells and the initial opening can be made with a local anaesthetic. One or two scientifically minded surgeons, notably Dr Wilder Penfield have taken the opportunity presented by this surgical requirement to perform certain experiments which have turned out to be of immense interest. With the patient's permission and co-operation Penfield stimulated selected exposed portions of their cortex with tiny electric currents. Moving round from sensory area to sensory area he found that his tiny electrical stimuli provoked characteristic sensations from the patients. In the visual areas they might see lights, colours, etc. in the auditory areas hear sounds, and in the temporal lobes get impressions of smells, taste, etc. Stranger still Penfield found that certain parts of the so-called association areas of cortex when stimulated, led to the patient recalling specific memories often of apparently forgotten items. One woman got a vivid impression of herself in a kitchen of a former home and hearing the voice of her mother long since dead. Others reported equally specific memories, sometimes with fragments of speech or

conversation attached quite often of items which the patients reported they hadn't thought of for years. One possible implication for this exciting work is as we have said that *all* information that has ever been put into the brain is stored as memory just in case it should ever be needed again. If this is so then to most psychologists the idea that the memory trace is laid down in the form of major structural changes in the cell body (such as with synaptic knobs) is no longer tenable. There simply aren't enough cells to cope. But suppose that the engram is laid down *within* the cell at sub microscopic level in the form of perhaps the rearrangement of the specialised molecular structure. Since no one has ever got a really good look at a molecule either in the nervous system or out of it this might seem to be a bit of optimistic guesswork, but there is in fact some strange evidence to back the idea up. To consider this we must acquaint ourselves with one of the lowliest creatures capable of learning—the little flatworm planaria. There is a good deal of argument about how far down the animal kingdom some form of learning can take place. Some workers even claim to have demonstrated memory mechanism in tiny single celled creatures such as amoeba or its hairy cousin paramecia, but you can be sure that any information stored was of the simplest and most rudimentary kind. It is when we get to the simplest form of worms and planaria is one of these that something closer to memory in the real sense can be clearly demonstrated. Typical of the kind of task which planaria manage albeit with a good deal of intellectual effort is to turn right rather than left at a little junction in order to get food or avoid an electric shock. They can also be conditioned to wince to a light being switched on when this is always followed by an electric shock—rather like Pavlov's dogs. Now planaria has the most rudimentary almost non-existent central nervous system. It has a front end shaped rather like an arrow with tiny light sensitive organs in it and which is clearly its head. It also has a back end which the charitable would call a tail. The question now is—in what part of the tiny body are memories laid down? The head would seem to be the most likely bet though you might feel it would be hard to tell for sure. At this point the psychologist makes use of another of planaria's interesting features—its ability to regenerate tissue with ease. Take a knife and slice off planaria's tail and both ends swim away one rather more efficiently than the other. Now in due course the head section will produce a new tail and—rather fantastically—the tail will produce a new head! Planaria can do other odd things too. Cut down the centre of its head without actually removing any tissue and in due course the two half heads will regenerate into two full heads producing a peculiar but rather neat looking creature. If one makes several flaps instead of just two you end up with lots and lots of heads on one body and get a very odd looking planaria indeed. All this is very interesting but the exercise has more point than this. In the first case ask yourself a question suppose you teach planaria a little maze and then slice the head into two. Now of the regenerating heads which has got the memory of the maze stored in it? Left, right, both, neither? Actually the answer is both and this should give some clue as to the answer to the next question. Cut a maze trained planaria in half (head and tail) and let the respective sections develop again into a full creature. One would certainly expect that the head part plus its new tail would be able to perform its little task without much trouble but what about the tail with its new head? The answer is that this too can run the maze. If this seems to be contradicting everything we've said about learning and the brain in general up to now then in a way it is. We must remember that planaria is an exceedingly simple creature with no CNS to speak of and no nerve cells of the kind found in higher animals. The engram wherever it is is certainly not formed by the development of synaptic knobs or by the modification of complex electrical fields. Furthermore as it is evidently stored in tail as well as head section, then it must presumably be laid down in most, if not necessarily all, of the animal's body cells. This is the point where the biochemists step in

and argue that it is not the outside but rather the internal structure of the cell that is modified through learning. Odd indeed but there is odder yet to come. Researchers got a collection of planaria and taught them a particular task—turning right in a simple maze and then took an equivalent number of planaria with no experience of this kind. They then collected the first group and whirled them round in a mixing bowl until all that was left was a homogeneous planaria soup and repeated the process with the other untrained group. They now fed the two kinds of soup (planaria will eat more or less anything that's hanging round) to different groups of totally untrained planaria and subsequently trained these in the original right turn task. This produced an extraordinary result. The planaria who had been fed the soup consisting of trained planaria seemed to learn the maze task significantly quicker than those who had been fed the untrained soup! You will know enough about experimental psychology by now to realise that these results caused immense controversy and a series of experiments were immediately launched by workers who had found the first result incredible. The controversy incidentally still rages as many of the attempts to repeat the experiments have not worked but the original protagonists still maintain the validity of their results. It is not hard to see why the critics get so hot under the collar for the implications of the findings if valid will throw into question just about every theoretical approach to learning to date. Since the planaria were thoroughly mashed up no neural connections or even any formal kind of organisation within the system would remain to carry the maze information across to the cannibal planaria. Furthermore one would have thought that the digestive processes of the cannibals would have completed the process of destruction. How then could the original maze habit or traces of it be possibly preserved and carried over? No one on either side of the argument has been able to offer up any convincing explanation except that if the results are valid then the maze habit in the case of planaria at any rate must be stored right down at molecular level—in other words at such a microscopic level that any mixing and digestion could have little or no effect on it. But even if the planaria results are valid would the same thing necessarily apply to humans? Not necessarily but if a process works for one living system it could in principle work for another and we must remember our conclusion that the brain enormous memory store suggests that modification of the neurone itself would be at too gross a level. It may well be that we shall find the brain puts down information in more than one way. There is reasonable evidence for example that many animals and humans are equipped with two kinds of memory store—a short term and possibly highly unstable one and a long term more or less permanent system. Information fed into our brains might go initially to the short term store where it is filtered for relevance or general usefulness. If unwanted for some reason it might be eliminated but if wanted passed on to the longer term system. Perhaps the short term memory (the kind that allows you to momentarily remember a new telephone number) is electrical and the long term biochemical neurological or both. At this moment psychologists and physiologists across the world are concentrating on these exciting problems and perhaps within the next few years we shall have some new answers and quite certainly some fresh surprises.

(i) Unsolved Problems

This section has attempted to raise some of the issues confronting psychologists in their attempt to solve one of the main mysteries of the brain—how information is stored and processed within it. Although a fair bit has been learned in the past decades it has really served to show that the problem is much more complicated than the earlier workers ever imagined. Furthermore you will have noticed that precious little has been said about how the information is extracted for the very good reason that precious little is known about this. Curiously some interesting clues are beginning to come from the study of computers

man's own specially created slave brains. These are already capable of storing quite immense quantities of information and engineers have been working steadily at improving the methods of storing information and of getting it out in a hurry. In recent years the computer engineers and the psychologists have been tending to get together and pool their ideas—with some interesting results (see *Sleeping and Dreaming* P 59-62). To more and more scientists it has become increasingly obvious that the study of the brain is real ground for interdisciplinary contact and that contributions to its study can come equally from psychologists, physiologists, physicists, engineers, mathematicians, educationalists and so on. The recently formed Brain Research Association for example is composed of scientists from practically every discipline with psychologists and physiologists who are traditionally the lumpins in brain science making up no more than 2.5 per cent of its ranks. Perhaps the really big problems in brain research will only come from multidisciplinary teams of this kind. But this is something of a digression and we must now pass on from learning and memory to the lesser but no less interesting problem of motivation.

IV MOTIVATION

(1) Why Does an Animal Do One Thing Rather Than Another?

This question aptly sums up the problem of animal and human motivation an important facet of modern psychological research. As is always the case with psychology perhaps more so than with other fields of science what initially seem to be straightforward questions designed to elicit straightforward answers become steadily more complicated on close inspection. The odd almost philosophical difficulties surrounding motivation are a good example. Why does an animal do one thing rather than another? Because it wants to is the stock reply—a reply which actually doesn't get anywhere at all. To say that the reason for doing something is because the deer *likes* it is no explanation merely renaming the problem so that it comes up in a different guise. It so happens that we tend to like doing the things we do though of course this doesn't always apply. We certainly like to eat but do we eat principally because we like it or because the food is essential to our survival? Perhaps the key is tied up here somewhere and the rock-bottom cause for all animal and human behaviour lies in the need to keep the individual creature alive. Well that will certainly do for food and water but it clearly doesn't work for other common activities such as sex. In the long term the survival of all living things depends upon sexual activity but animals certainly don't understand this and humans only found out the link between the sexual act and conception a millennium or so ago. And anyone who believes that people indulge in sex solely to allow the human species to survive is very naïve indeed. Now the situation gets even more complicated. It seems as if we make love because we like it with the long term result being that the species survives. But what can be the link in physiological terms between liking something and it doing us good? And just to complicate matters even more supposing that we accept this link how do we explain other common patterns of human behaviour? Why do some people like going to football matches or art galleries? Why don't they go there to eat the footballers or the paintings and how is the survival of the human species helped by such practices anyway? Having muddled the issue thoroughly—or rather showed it up in its true light—we can now go on to see how psychologists have set to work to try to unravel it. They have not got very far but they have got somewhere.

(2) The Mechanical Tortoise

The first people to face up to the problems raised above were the Behaviourists. In their gallant attempt to explain human and animal behaviour in mechanistic terms they realised that

they would have to account for the tendency of animals to set out to do things rather than simply engage in random diffuse activity and they thought this could be fairly simply handled. They were most anxious of course to avoid explaining different types of behaviour in terms of different goals—to suggest that an animal had got a goal in mind was to imply that it had a mind and furthermore some kind of picture of the future in it. To begin with they took the simplest possible form of mechanical analogy. Imagine a clockwork mouse which when wound up runs across the floor. What caused it to do so? The clockwork and the energy tied up in the spring of course with its direction determined by such matters as the orientation of its wheels, the angle of the floor etc. Anyone saying that the toy crossed the floor because it wanted to would be being silly. Similarly the Behaviourists stated one should be able to avoid the same kind of inference when observing the movements of a real mouse. If the response is that the real mouse can do a good deal more than just run across a floor—can squeak, change direction, avoid cats and eat cheese—then the reply in essence is that one could build a mechanical mouse to do that as well provided one had the time and ingenuity. The more complicated and versatile the mechanical mouse the harder it would become to tell the difference between the two and when one had two apparently identical mice would one still talk about one wanting to cross a floor and the other doing it purely automatically? Was there an important difference anyway? Critics of Behaviourism argued that indeed there was a difference. The real mouse ate the cheese because it satisfied a need for the food whereas the mechanical mouse no matter how many bogus sounds of enjoyment it made as it munched the food was merely going through an essentially meaningless mechanical process. This is a dangerous argument for suppose that one decided to power the artificial mouse not by clockwork but by the combustion of cheese and made it so that it would stop when its inner store of cheese ran out. One would now have an artificial mouse with a need for cheese as great as that of its biological counterpart. If this seems an unlikely step to take consider the case of Grey Walter's mechanical tortoise. In an effort to replicate some of the conditions of behaviour the great English psychologist Dr Grey Walter of the Burden Neurological Institute constructed a tortoise which exhibited some of the paramount properties of living creatures. His tortoise—a shell on wheels with no pretensions to looking like an animal—was powered by storage batteries which drove a motor allowing it to run around on the floor. Its movements were far from aimless for it was also equipped with photocells in its head capable of detecting areas of light or dark. A series of simple switches inside were arranged so that when the tortoise's batteries were fully charged the device would move towards dark areas of a room, finding its way underneath chairs and tables carefully working its way round books, human feet etc. placed in its way. With batteries low a different switching arrangement would come into operation and the device would now tend to avoid dark areas and seek out light ones—in particular the light inside its "hutch" where a battery charge was conveniently situated. Once inside the hutch Grey Walter's tortoise would connect up to the battery charger later emerging replenished to set out for dark places again! Here the Behaviourist argument emerges most strongly. It is not of course that Grey Walter had manufactured a living thing—no one is making that claim—but rather a matter of whether the tortoise's tendency to seek out its battery for recharging etc. constituted a need in the same sense as does the real mouse's need for cheese. This is a big question which you will probably have to think out for yourself. In the meanwhile let's see how the Behaviourists attempted to translate animal behaviour into similar terms.

(3) Drives and Needs.

The Behaviourist position can be summed up as an attempt at describing animal behaviour in the

simplest possible way and to do this they evolved the concept of drives. A drive is described as something which causes an animal to perform a particular act and the ideal position from the behaviouristic viewpoint would be to find that all animal activity could be explained in terms of a limited number of drives. To begin with things looked simple and promising for it appeared as if a drive could be thought of as something that promoted bodily well being. For example when an animal is short of food it is running out of power. This causes a sensation known as hunger which signals a bodily need and this in turn sets in motion a chain of activity which culminates in eating. When the food has been ingested the need is satisfied the hunger vanishes and the drive is reduced. The same argument applies to thirst and with a bit of modification to sex. In the latter case if an animal does not engage in sexual activity for a given period of time certain substances build up in the body, the hormonal system becomes unbalanced etc. and a need builds up in the body which gives rise to a drive. This in turn pushes the creature towards sexual activity with a suitable mate. Carry this on just a bit more and include a need to escape painful situations and you've practically got the whole of animal behaviour sewn up. What's more it is sewn up in a very convincing way because the needs and drives are not vague and ambiguous, but relate directly to vital bodily processes which if not operating properly will cause the animal's death. All animal behaviour could be explained in terms of a drive to (i) reduce hunger, (ii) reduce thirst, (iii) reduce pain and (iv) achieve sex. To those who didn't want to talk about achievement which seemed to imply that an animal was actually setting out to do something then the final one could be rephrased (iv) to reduce sexual tension. An animal in a state of need would be activated by some or all of these drives and would continue to behave until all drives were reduced. Proponents of this delightfully simple point of view even showed how learning theory could benefit from drive reduction ideas: a pattern of behaviour or conditioned reflex would be established they claimed if at its conclusion a drive was reduced. If no drive reduction took place then the behaviour pattern would not be learned. In the thirties and forties a number of mathematically inclined psychologists even attempted to express this in the form of sets of equations which looked enormously impressive on paper but which also bore little relationship in practice to the way living animals actually behaved. For example people soon realised that a bit of a problem emerged for an animal if all its drives were set at maximum as it were and all the appropriate drive reducing stimuli were at hand. Take a rat, severely deprived of food and water and place it in a cage with both available. What is it going to do first eat or drink? Presumably it will be pushed in the direction suggested by the strongest drive. Using this as an idea it was decided that it ought to be possible to rank animal drives in order of strength by a simple test. Place a rat deprived of either food water or sexual activity in a box facing the necessary drive reduction stimulus across an electrified grid. Now how strong an electric shock is the rat prepared to put up with in order to fulfil its need? Experimenters found that thirst was the most effective stimulus food next and sex third. This was all fine until they found that rats satiated in all three modes would still occasionally cross the grid even when there was nothing on the other side! Now what kind of drive could be operating here? Furthermore they found that an animal again supplied with plenty of food water etc. would still run through a complicated maze and learn it pretty well despite the lack of drive reduction at the other end! Before long the theorists found themselves rather glumly proposing exploration or curiosity reducing drives to account for the well known fact that animals like to roam about all over the place. This naturally allows one to have a completely comprehensive theory of behaviour and learning in drive reduction terms, but with the penalty of converting a simple fairly sharply defined theory tied closely to describable bodily requirements, into a complicated diffuse

and far less convincing one. If any activity not explained in terms of the original drives can now be accounted for in terms of a reduction or an exploratory drive then one has an explanation of the behaviour. But to many people's minds it is no better than those around before the whole concept of drives and needs was introduced. Similarly there was a certain neatness and utility to the idea that a pattern of behaviour could be learned if at its conclusion a drive such as hunger or thirst was reduced. This neatness vanishes when we are told that an animal has learnt something else because its curiosity was satisfied or the opposite that it was not learnt because its curiosity drive was *not* reduced! Clearly the root of all these difficulties lies in the refusal of many psychologists to admit that a creature or a person does something or learns something because it likes it. Fair enough. We have already pointed out how subjective is the idea of an animal doing something because it wants to and the job of the psychologist is to try to define behaviour objectively rather than subjectively. What was clearly needed was some definable describable physiological process which could correspond to pleasure and until this was found psychologists could proceed no further in the field of motivation. In 1954 experiments were published which gave them the green light.

(4) The Pleasure Centre

The arrival of microelectrode recording techniques allowed numerous experimental studies of the animal and even occasionally the human brain in action to be made. In a prolonged assault on the inner intricacies of the cerebral cortex and lower control centres psychologists and physiologists began the elaborate job of mapping the brain defining as rigidly as they could which areas were devoted to what function. In many cases the areas they stimulated seemed to be silent i.e. provoking no obvious response from the animal. Others however were more dramatically active. In 1956 the American James Olds and the Englishman Peter Milner were studying the responses of rats with electrodes implanted in what is known as the septal area of the brain a spot beneath a body known as the corpus callosum. Animals stimulated with low voltage electric currents in this area seemed to behave in an odd way—almost as if they were enjoying the experience. For many years it had been known that stimulating the area known as the hypothalamus could produce symptoms of rage in animals the creatures responding as though angered or threatened the sham rage switching off immediately the electric stimulus ceased. Similarly areas had been found which when stimulated would cause dozy apparently sleepy behaviour. Now here was something very different and Olds and Milner began to suspect that they had hit on something akin to a pleasure centre. To test this they designed a weird electrical circuit surely one of the oddest ever to be seen in a laboratory. From the electrode in the rat's septal region a wire ran to the battery providing the electrical stimulus. In the rat's cage they placed a lever and connected this to the battery in such a way that when the lever was pressed the battery emitted a single pulse thus allowing the rat—if it wanted to—to stimulate this particular area of the brain. Although they had half suspected that the rats might occasionally give themselves a jolt in this pleasure area no one had anticipated the extent of the rats' involvement. All animals once they had discovered the trick of pushing the lever went into a sustained surge of lever pressing keeping the activity up for literally hours on end. In fact there was some suggestion that they might have kept it up for ever had not physical exhaustion sooner or later intervened. Given the choice of alternative levers providing food water or the chance to stimulate their septal regions all rats reliably chose the latter even those who had been substatistically deprived of opportunities to eat or drink for some time. The lack of apparent satiation of the effect was one of the really odd things about the discovery. No human or animal appetite has ever been found which cannot be

satisfied if only for short periods. Only where some severe pathology is involved such as with a disease or brain tumour do the normal appetites remain unquenched. But here was something quite different—an appetite which seemed to have boundless depths and which outrode any of the other paramount needs of the animal. It was for this reason that Olds and Milner hypothesised that they had hit on the centre in the brain which mediates the sensation which we humans know of as pleasure. How surprising is it that some such centre exists? Not very. When we do something we like be it eating drinking or even going to a football match then the feeling of pleasure that we get must be matched by some parallel process in the brain and it could well be that this is located in some convenient but specific centre. Olds and Milner incidentally found that their animals would very swiftly learn a task if they were rewarded by a session on the pleasure centre and here perhaps another important point emerges. There has always been some evidence though the matter is by no means settled that learning was somehow improved if following the performance of the desired task a reward such as food drink, sex etc was given. The big question is what kind of signal is given to the memory system to denote when something is to be permanently laid down? Olds and Milner appeared to have provided one possible answer and one that would have greatly satisfied Pavlov Watson and their immediate successors the reinforcing stimulus—the message that declares that something will be learnt—is a message that has passed through the pleasure centre. The validity of this idea is still uncertain but it has the merit of answering an age old question in reasonably simple fashion and also of helping us towards the solution of an even more venerable philosophical one—the nature of pleasure itself.

(5) Emotion

This is one of the most misunderstood words in the psychologist's vocabulary and is a source of endless confusion. The trouble is it means so many things to so many different people. To the psychologist however it has a fairly specific meaning and we must try to get some idea of what this is. Only by doing so can we avoid falling into such traps as to say 'Animals cannot feel emotions' or 'Computers can never think because they have no emotions'. First let's attempt to nail the word 'emotion' to the wall and try to analyse it. When we talk of people being emotional what exactly do we mean? That they tend to weep a lot get easily angered? Sorrow and anger are emotions that is clear. But is not love an emotion too? Do we mean that emotional people tend to fall in love a good deal? Or do we mean that their love is deeper than others—or perhaps shallower? Already some confusion is creeping in. Let's ask now how we know that someone is emotional or in an emotional state. The answer is probably that they exhibit a characteristic behaviour pattern which allows us to judge. If they wave their fists go red in the face and shout then we might infer that they were angry. Of course they could be acting and merely pretending to be angry in which case what is the dividing line between the real and the simulated emotion? The answer would seem to be that the latter was not accompanied by an internal *feeling* of a special kind and this now tells us that there are at least two sides to emotion—subjective psychological state and an external physiological one. In fact psychologists find it convenient to consider three aspects. The first is the *behavioural*—is the kind of activity in which the angry or otherwise emotional person engages. This is generally easily detected and is of the waving arms around variety. The second is the *physiological* which consists of considerably more discrete behavioural signs not always obvious to the observer but which may be detected by suitably sensitive instruments. The third is the *psychological* or introspective and this refers to the state of mind of the individual when he is angry or whatever. This of course cannot be directly sensed by other individuals who rely on the angry person reporting to them. How

he feels. How are these linked together and what function do they serve?

(a) The Behavioural

If you fire a pistol behind someone's back they exhibit a very characteristic response the most common feature of which is that they jump some distance into the air. This may seem desperately obvious but actually there is a good deal more to the response than that. High speed photography shows that all human beings respond to sudden loud noises by a highly predictable behavioural sequence of which the jump is just one part and which bears the name the startle pattern. It includes a marked hunching of the shoulders closing the eyes baring the teeth and raising the hands in the direction of the face. It doesn't take long to see that these actions which occur reliably in all human beings are not random and pointless but serve to help the individual respond rapidly to a dangerous situation. The jump is an alerting response the eyes are closed to protect them the hands raised in defence or perhaps to strike the teeth bared possibly as a threatening or warning sign. Similarly at a more common emotional level the waving fists and loud voice of an angry man equip him to some extent for battle. And what of the tears and the cowering posture of a thoroughly frightened individual? Well these in some way suggest to the aggressor that the battle is over and are signals to him to stop fighting. Men being natural fighters tend to do little in the way of crying and will generally scrap on until they are physically incapable of continuing. Women on the other hand who are not particularly strong or well equipped to fight tend to slip into weeping and submission rather easily hence the well known fact that tears are a woman's strongest weapon against a man. (This submissive pattern of behaviour falls dismally of course when the aggressor is a carnivore such as a tiger when the one submitting is eaten, tears and all.) The very obvious facial expressions made by people in various emotional states led the great Charles Darwin to the view that the type of face made was a good index of what emotion the individual was in the grips of. To test this idea psychologists took photographs of the facial expressions of people in various emotional states and then asked other people to try to name them. The results were poor with few people doing better than chance. The only expression reliably recognised and correctly assigned to an emotion was a smile and even this was occasionally confused with other emotional states such as pain, or even fear. The same experiment performed with movies yielded somewhat better results and when sound was added results were again improved. The clinching thing however seems to be the setting in which the behaviour takes place for people become very accurate at judging emotions when they see the surroundings in which the other people are behaving. Clearly the external signs of emotion, despite their immediate and rather obvious manifestations, are an unreliable guide to what is going on inside the individual's head. The same argument incidentally applies to animals though somewhat less forcefully. Most animals give pretty explicit signs when they are angry or when they are afraid. One can even detect something suspiciously like guilt in the general pattern of behaviour of a dog which has done something it shouldn't. But can one really talk of a dog feeling guilty? If not—why not? Whatever answer you give will be quite as valid as any given by a psychologist.

(b) The Physiological

The signs and signals we talked about above were all gross obvious, and yet as we pointed out somewhat unreliable. To a large part they seem to be the outward manifestation of an internal process which at the same time serve a useful purpose as when the startle pattern alerts the individual into a posture suitable for defensive or aggressive action. But what are the finer physiological manifestations of emotion? These must obviously involve changes in the state of bodily and cerebral activity. Psychologists have pinned down no fewer than 11 distinct facets of human and animal behaviour which give a clear

index of changes in emotional states. To give some idea of the complexity of emotional behaviour we will look at each of these briefly.

(1) The first and perhaps the most obvious is heart rate. The heart's job is to pump blood around the body and the blood provides the vital organ supply to the brain. The more intense the activity the more oxygen is consumed and the more the blood needs to be circulated. It should be no surprise therefore to anyone to learn that as activity is stepped up so heart rate increases and vice versa. Furthermore heart rate tends to accelerate just prior to some important or exciting piece of activity or even on merely thinking about it and this means that we have here one index of emotional state. A device known as the electrocardiogram (EKG) can give a very precise picture of heart fluctuations and represents one objective way of plotting this information.

(2) We have already implied another measure: respiration. This increases more or less alongside heart rate and is a pretty good index of most emotions. Irregularities of breathing including variations in the depth of breaths are a particularly good index of nervousness as most people know and all this can be detected by a suitable instrument.

(3) More or less hand in hand with the above come changes in local blood pressure and volume. The facial accompaniments of which—blanching or blushing—are only too obvious. These can be measured by a device known as the plethysmograph which is merely a version of the kind of device a doctor uses to measure your blood pressure in a routine medical examination.

(4) A somewhat harder emotional symptom to measure but very characteristic of most emotional states is muscle tension and its associate tremor. In anger rage and other aggressive states muscles become tensed to be ready for rapid action and if this is carried too far we get trembling of the limbs—a familiar accompaniment of great nervousness or fright.

All the above are easily discernible indices amenable to instrumentation but not depending upon it. The remaining manifestations are harder to detect though just as valuable once one has caught them. Beginning with the most obvious we have:

(5) The pilotomotor response which is a hangover from the days when our ancestors had a good deal more hair than we do today and which can be seen when a cat's fur fluffs out in rage or fear. In humans today we call it 'goose-pimples' and it is often a precursor to the feeling of full blooded fear.

(6) Even harder to measure is salivary secretion which is the kind of response Pavlov studied with his dogs. In anxiety or fear the saliva flow tends to be inhibited and we find ourselves with dry mouths.

(7) An index of emotion which is particularly obvious to the individual is the change in gastrointestinal motility. Movements of the stomach and intestine are brought to a brief but definite halt in strong emotional states with a complementary and often rather dramatic surge back to action shortly afterwards. There are plenty of homely and slightly vulgar expressions to describe the consequences of this.

(8) There has been a recent rise of interest in the pupillary response as an index of certain types of emotion. The pupil of the eye tends to dilate in moments of anger or pain with slight dilation occurring during periods of interest in something. This has led some clever psychologists who work in the advertising profession to use this as an index of the relative effectiveness of different

types of advertisement. All the subjects have to do is look at the subject matter while a recording camera photographs the pupils of their eyes from a distance.

(9) Because the endocrine or glandular system is active in emotional states the chemical constitution of the blood changes markedly as the hormones flow within it but this index while potentially useful is of course abnormally hard to measure directly.

(10) Next we come to the so called galvanic skin response (GSR) which is in fact nothing more than the electrical resistance of the skin. For various reasons not properly understood the resistance of the skin to an electrical current changes with most emotional states tending to decrease as a function of the intensity of the emotion. This can be detected with a suitable instrument and meter and is perhaps particularly interesting because it is an automatic response which the individual is not consciously aware of. Connect someone up to a GSR meter tell him that you are going to stick a pin in him and the needle will swing wildly. It is a very effective demonstration of an entirely involuntary response and is generally one of the first experiments that fledgling psychologists perform on each other in their laboratory classes.

(11) Finally there is the EEG which we referred to earlier on (see Q5). The electrical activity of the brain does change with varying degrees of bodily activity though what these changes mean is a matter for skilled interpretation.

(c) *The Psychological*

You will have noticed that many of the above indices—stomach motility muscle tension, etc.—have definite physical accompaniments which are only too obvious to the individual experiencing the emotion and it should not be too surprising in the light of all this that an emotional state markedly alters our physical and psychological feelings and sensations. But is this all there is to emotion? Can the age old human passions of love and hate be reduced to permutations of salivary secretion blood pressure pilotomotor response and electro cortical activity? Put so baldly of course the answer is no. Love demands a partner a setting a trigger and some temporal span—as does hate. In humans these require the active participation of the complex computer we call the brain and a background of education social activity and some awareness of goals other than the immediate. Nevertheless the intense physiological and psychological changes which envelop us when we are in love or when we fight in passion contribute the better part of the powerful sensations we feel. But which of the three faces of emotion, the behavioural the physiological or the psychological is the real or most significant one?

The answer is that no single one predominates for emotion is a complex of all three. When the object of our emotion be it love hate or what ever is first encountered then mind and body combine to set the individual up for the optimum pattern of responses. This involves some permutation of physical change which naturally is reflected in psychological changes of mood. These in turn provoke outward changes on a larger scale which may involve combat or the ritual of love. If this description seems to debase the concept of human emotional response then this is a pity for there is no reason why it should. The powerful forces that thrust men into the numerous passions of the world would have no meaning were they not accompanied by potent changes in bodily state. The astrality that springs from these passions is no fraction diminished because we can identify the physiological and psychological changes that accompany and to some extent determine them.

It will have occurred to you that in this section on motivation we have drifted closer and closer to another of the critical areas that psychologists

study—the nature of human personality. Psychologists know far less about this area than they would like to but their century of scientific activity (a small span compared with the history of the more traditional sciences such as physics) has begun to pay off. In the next and final section we will take a look at what they have done or have tried to do in this most fascinating of areas.

V PERSONALITY AND THINKING

(1) What Constitutes a Person?

To many people this is the most important single question in psychology and indeed perhaps in the combined fields of science and philosophy. What is it that makes up that unique blend of psychological and physiological factors we call personality? The answer is predictably complicated and before we can even begin to consider it we must attempt to define the problems in the field. In the first place let us consider the most venerable and apparently simplest answer—a person is that thing in the head that thinks, feels, is aware of itself as an individual entity and which controls a brain and body. This is the answer which probably fits best with the non-technical philosophy of the man in the street and which matches also with a long standing traditional view fostered by the majority of systems of religious belief. Put another way it states that human beings are composed of essentially two parts. One of these is physical and consists of the body and its control centre—the brain. The second is non-physical and is called the mind, soul, spirit or some similar name. This is a separate entity which controls the body through its brain and while involved in this way must obey the laws of the physical world. It may however survive the death of its body (one of the most widespread of religious views of personality) and occasionally as with telepathy, precognition etc. may step outside to contact other similar minds in other parts of the world or even take a peek into the future. As we have said this is an exceedingly widespread view of the nature of personality and it will be the one held by many who read this article. This is now the point where you could ask whether this view is acceptable to psychologists and that is a fair and proper question. It requires however two separate answers. In the first place some psychologists though certainly not the majority accept this or some very similar view but on an entirely personal plane. When they think as scientists however most are inclined to disagree with it. Nothing that has been uncovered in the history of experimental psychology with the possible exception of the very dubious evidence for telepathy suggests that the human personality is a separate entity to be considered in isolation from brain and body. Psychologists who choose to believe otherwise frankly admit that they do so on the basis of faith or hunch and argue that even though the scientific facts appear to contradict their beliefs at the moment perhaps in due course experimental psychology will uncover fresh new material to change the whole picture.

Does Mind Exist?

An increasing number of psychologists and brain scientists today take a hard line on the spiritual view of personality but does this mean that mind does not exist as the Behaviourists strove so hard to prove? Certainly not. There is clearly a whole range of rich psychological activity which cannot be explained simply in terms of bundles of conditioned reflexes and the like. What seems to have happened in fact is that as animals have evolved via the remorseless processes of evolution, so more and more 'power' has been given to the cerebral control centres. At some stage in the evolutionary ladder—it is very hard to say exactly where—the brain ceased to be a purely automatic device and some glimmerings of what we call consciousness began to appear. In the early stages, this probably merely took the form of a switch in the brain which allowed the creature to select from one or two alternative modes of action. This capacity would imply

some system within the brain capable of making a comparison of the two modes and thus of standing back from itself. Increase the complexity of the brain and its capacity to select, predict and determine and you will see that the evolution of a higher control centre capable of inspecting ongoing activity will emerge. Thus could the thing we know of as consciousness develop. Incidentally if you feel that such an abstracting self-inspecting system could not be conceived in purely mechanical terms then you are wrong for the latest developments in computer technology have been devoted to achieving this. But before getting caught up in arguments about whether computers could think (we'll tackle this briefly later on) let us just summarise the current approach to the problem that most psychologists accept today. Mind is a phenomenon which has arisen almost inevitably as brain complexity and power have increased and its function is to select alternative activities and compute the consequences. Just as human bodies and brains differ in countless ways so human minds subtly moulded over the years from infancy to adulthood differ too. The result is that the world is populated with a large number of human beings united as a species but each one an individual entity compounded of body, brain and mind. All three are equally real, equally important—and equally helpless without each other's company. Let us now take a look at the principal forces which serve to mould these individual entities we call people and some of the essential ways in which they differ.

(2) Interplay of Heredity and Environment.

People and animals differ in a large number of ways and are alike in others. We share certain features—upright posture, well developed brains etc.—with other primates, such as chimpanzees. We also share certain features—binocular vision, mammalian reproduction techniques etc.—with white rats. We even have a limited amount in common—respiratory systems depending upon oxygen need to ingest some kind of food etc.—with creatures as lowly as the earthworm but nothing with cabbages or oak trees except perhaps a dependence upon sunlight. Now what is it that determines these similarities and differences? The answer is summed up in the word heredity. Creatures of particular species mate with each other and hand on to their offspring via the genes and chromosomes the physical characteristics of the species (see F31). They may even hand on certain predetermined patterns of behaviour which we have earlier referred to as instinct (see also F38). Broadly speaking, the lower down the phylogenetic scale the more behavioural information is carried over via the genes, and the less flexible is the creature's ultimate behaviour pattern. Earthworms, for example, come into the world fully equipped to go about their simple business on this planet. They present almost identical faces to the world around them, and taking it all in all they change little from birth to death. Earthworms are largely the product of heredity, the principal forces which mould them being in the genes of their parents and the incredible long history of their species stretching back for hundreds of millions of years. At the other end of the continuum we have human beings whose physical characteristics and a very limited number of behaviour patterns are inherited but whose personalities and individualities (unlike the earthworms) change significantly throughout the span of their lives. These changes are the consequence of the impact of the environment on the flexible human brain, a flexibility which allows human beings to respond swiftly and intelligently to the changing hazards and opportunities of the world. It should be clear therefore that the basic differences that so obviously exist between the personalities of different people reflect the experiences that each individual has had in his or her lifetime. See a newborn child and search for signs of its personality. You will look for a long time to no avail. But watch a child grow from infancy to adolescence and you will see the personality slowly building and emerging—more or less hand in hand with the young person's growing awareness

of his own individuality his strengths and his weaknesses

Twin Studies

Striking evidence of the immense influence that the environment has on us comes from the famous studies of identical twins performed in America by Newman in the 1930s. There is a bit of confusion in most people's minds about what actually are identical twins as opposed to the ordinary born on the same day variety. In the case of the latter—known as fraternal twins—what has happened to produce the happy event is that during conception two of the eggs in the mother have been fertilised and thus two babies are born. Without going into too much detail this means that two quite separate creatures develop, each being equipped with the random genetic mix that follows the meeting of the father's sperm with the mother's egg. The children when born may be of different sex, different colour, hair, eyes etc. and are likely to be no more alike than would be brothers or sisters born in different years or even decades. Each therefore begins with a different hereditary pattern as determined by the genes. With identical twins a curious fluke occurs. By some process after conception and after gene mixing has taken place, the fertilised egg splits, amoeba fashion, and two babies begin to develop—but both have identical gene patterns and thus up to the moment of birth can be looked upon as totally identical human beings. This weird identity is as we all know frequently carried on throughout the twins' lifetime even though it is generally noticeable that the similarities become less marked with age. Now to return to Newman's experiment. Nineteen pairs of identical twins were found (a good deal of research was needed) who had for one reason or another been reared apart from an early age and had grown up in different environments. Newman found that while the adult twins maintained a striking physical resemblance, the personalities of the pairs seemed in many cases to have moved apart. In one case the first of the pair had been successful in worldly terms, had acquired a college education and was happily married with a stable family while the second had been less fortunate and was leading a rather unsatisfactory life in an unskilled job in a working class neighbourhood. Twin A seemed optimistic, good humoured and more dominant a personality while twin B was morose, lethargic and lacking in self confidence. Similar observations were in general noted with other twins particularly in cases where one of the pair had been reared in a more stable and economically more satisfactory environment. No better illustration of the relative influence of heredity and environment on human personality can be found than in studies of this kind. But is it only physical characteristics that are genetically determined? Is none of the psychological make up of the individual built in to him at birth? We can answer this by saying that twin studies have shown that while personality is certainly modified by the environment there is a good deal of evidence that intelligence is relatively untouched by normal environmental differences. Newman and his colleagues for example found that there was a higher correlation between the IQ test scores of identical twins reared apart than there was between fraternal twins reared together—a finding which suggests very strongly that intelligence whatever that may be is largely carried over in the genetic system and bequeathed to the individual at his birth. If this seems to be contradictory or terribly unlikely then there is probably some confusion over the meaning of the word intelligence and since it is one of the fundamental themes making up the fabric of human personality we will take a closer look at it.

adjustment which is another way of talking about the kind of flexible response to the environment which is so characteristic of humans. This of course means that we can talk of animals having some degree of intelligence and most psychologists nowadays would agree that this makes sense. The only problem arises if one considers intelligence to be metrixically tied up with consciousness, thought, language etc. which of course it is not. Certainly the ability to communicate in linguistic terms and to think in abstract modes are signs of a highly intelligent creature but some degree of intelligence may be present without those traits. Probably one could even talk of intelligence being present in any animal that could modify its behaviour in response to the environment and repeat this behavioural response at some later date. This means as you will have gathered that intelligence is present in any creature that can learn including our little friend planaria. It is of course a very limited form of intelligence and planaria would not come out with much of an IQ (intelligence quotient) if submitted to human IQ tests. The structure of these tests incidentally becomes comprehensible if one sees them as measures of human flexibility rather than of knowledge. The standard IQ test which forms the basis of the much reviled 11 plus exam is an attempt at getting some idea of an individual's general flexibility rather than how much information is actually crammed into his head. Without getting involved in the educational argument here the point is that a test of the child's inherent capability is more likely to give some index of his fitness for higher education than is a test of his knowledge and thus is what the IQ test attempts to sort out. Hence the relative uselessness of cramming to prepare for the 11 plus and the surprise results it sometimes produces. You may think you see a bit of a contradiction here. On the one hand we have said that intelligence whatever it is seems to be built in the individual and is something to do with his basic brain power. In this case why are new born babies not fully intelligent at birth? The paradox is solved by saying that the peak of intelligence is not reached until the brain is fully mature (at about 18 years of age in homo sapiens) after which it begins to decline remorselessly with increasing age. Thus you will find that scores on IQ tests are weighted according to age. For very young children considerable allowance is made for age and their raw score is upgraded according to a standard scale. So too is the score for older people who inevitably score lower in IQ tests than do 18 year olds. Thus we find that a university professor aged 60 would produce a far lower raw score than a young student of equivalent intelligence—even though the venerable professor's head contains far more knowledge! If this seems odd remember that it is the individual's potential and general flexibility that the tests are all about and not the depth of his fund of knowledge. The IQ test itself is a rather arbitrary affair and was arrived at in the first place by a group of psychologists selecting a bunch of questions which they felt best tested this rather elusive faculty of flexibility. They then arrived at a scoring system which achieved the result that if you tested a large number of people drawn randomly from the population, their average score would equal 100. In fact this is exactly what an IQ of 100 means—it is the average score of the population at large. This has led to the sarcastic observation of one psychologist that intelligence was that faculty that is measured by intelligence tests! This is a witicism with some truth in it but nevertheless the IQ has a practical value notably as a sorter out of the bright from the dull in a situation where environmental or social backgrounds might have intervened to cloud the issue. The 11 plus is one such example as is the fact that the IQ test taken prior to university entrance is the best known predictor of success in final degree examinations—at least in the USA. On the other hand as you may have suspected social and cultural factors can influence IQ scores thus suggesting that they are not as pure as might have been hoped. Tests conducted on white and black children in America in the 1960s, for example, showed a marked difference in IQ between the two racial groups—the whites coming out pretty clearly ahead. This

(3) Intelligence and IQ Testing

Psychologists have spent a good deal of time arguing about what exactly is meant by intelligence and it is not worth covering this battle-scarred ground again. One definition which makes a good deal of sense is versatility of

adjustment which is another way of talking about the kind of flexible response to the environment which is so characteristic of humans. This of course means that we can talk of animals having some degree of intelligence and most psychologists nowadays would agree that this makes sense. The only problem arises if one considers intelligence to be metrixically tied up with consciousness, thought, language etc. which of course it is not. Certainly the ability to communicate in linguistic terms and to think in abstract modes are signs of a highly intelligent creature but some degree of intelligence may be present without those traits. Probably one could even talk of intelligence being present in any animal that could modify its behaviour in response to the environment and repeat this behavioural response at some later date. This means as you will have gathered that intelligence is present in any creature that can learn including our little friend planaria. It is of course a very limited form of intelligence and planaria would not come out with much of an IQ (intelligence quotient) if submitted to human IQ tests. The structure of these tests incidentally becomes comprehensible if one sees them as measures of human flexibility rather than of knowledge. The standard IQ test which forms the basis of the much reviled 11 plus exam is an attempt at getting some idea of an individual's general flexibility rather than how much information is actually crammed into his head. Without getting involved in the educational argument here the point is that a test of the child's inherent capability is more likely to give some index of his fitness for higher education than is a test of his knowledge and thus is what the IQ test attempts to sort out. Hence the relative uselessness of cramming to prepare for the 11 plus and the surprise results it sometimes produces. You may think you see a bit of a contradiction here. On the one hand we have said that intelligence whatever it is seems to be built in the individual and is something to do with his basic brain power. In this case why are new born babies not fully intelligent at birth? The paradox is solved by saying that the peak of intelligence is not reached until the brain is fully mature (at about 18 years of age in homo sapiens) after which it begins to decline remorselessly with increasing age. Thus you will find that scores on IQ tests are weighted according to age. For very young children considerable allowance is made for age and their raw score is upgraded according to a standard scale. So too is the score for older people who inevitably score lower in IQ tests than do 18 year olds. Thus we find that a university professor aged 60 would produce a far lower raw score than a young student of equivalent intelligence—even though the venerable professor's head contains far more knowledge! If this seems odd remember that it is the individual's potential and general flexibility that the tests are all about and not the depth of his fund of knowledge. The IQ test itself is a rather arbitrary affair and was arrived at in the first place by a group of psychologists selecting a bunch of questions which they felt best tested this rather elusive faculty of flexibility. They then arrived at a scoring system which achieved the result that if you tested a large number of people drawn randomly from the population, their average score would equal 100. In fact this is exactly what an IQ of 100 means—it is the average score of the population at large. This has led to the sarcastic observation of one psychologist that intelligence was that faculty that is measured by intelligence tests! This is a witicism with some truth in it but nevertheless the IQ has a practical value notably as a sorter out of the bright from the dull in a situation where environmental or social backgrounds might have intervened to cloud the issue. The 11 plus is one such example as is the fact that the IQ test taken prior to university entrance is the best known predictor of success in final degree examinations—at least in the USA. On the other hand as you may have suspected social and cultural factors can influence IQ scores thus suggesting that they are not as pure as might have been hoped. Tests conducted on white and black children in America in the 1960s, for example, showed a marked difference in IQ between the two racial groups—the whites coming out pretty clearly ahead. This

was greedily seized on by racialists as demonstrating the innate superiority of the white children until it was pointed out that the selection of the two samples was faulty: the black children had been drawn from rural parts of the south while the whites came from the urban north. When a repeat experiment was performed drawing the whites from the rustic south and the blacks from the northern cities exactly the reverse finding emerged: killing one age-old notion and at the same time highlighting the fact that IQ tests were vulnerable to social and cultural factors. Incidentally for those who like to pursue racial arguments it is interesting to note that the highest IQ ever recorded by standard tests—a shattering 200 was scored by—a young Negro girl. When considering the world as a whole however the fact remains that humans are very heavily divided from each other by a barrier potentially more difficult to surmount than those of race class or creed—intelligence. Furthermore the gulf is one that is particularly difficult to bridge because of lack of incentive on either side. A highly intelligent person generally finds the company of a rather dull person quite unacceptable and the reverse is also true. Also the differences between high and low IQs are likely to become more apparent in the coming decades as the old barriers of class etc which used to mask intelligence dissolve. From this important aspect human personality we now move on to consider the nature of one of the processes most characteristic of human brains—thought.

(4) Thinking

We have suggested that personality is an amalgam of the various faculties which are associated with cerebral activity and that variations in personality reflect variations in the individual's environmental history. Any creature with a reasonably flexible set of responses to its environment can therefore be said to have some rudimentary personality and many of us can detect this in our domestic pets. If this seems a peculiar notion then this is only because we have erroneously tended to think of personality as being a solely human trait rather in the way that people dismiss animals in general as having no intelligence. But what is it that does distinguish us from other animals—do we differ merely in terms of the capacity and computing power of our brains? Probably the answer is yes, though it has to be recognised that the gulf is pretty wide. Yet if one looks at the cerebral equipment of say a chimpanzee one gets the feeling that there shouldn't be *that* difference! Furthermore if one comes closer to home and looks at some of our ancestors such as Neanderthal or Cro-Magnon Man it is hard to account for the differences between their primitive lives and ours today. Certainly we exist 100 000 years later in time and it would be a bit pathetic if we hadn't progressed since then. But the same argument surely should apply to chimpanzees who do not seem to have developed much in the same period and the whole thing seems even odder when we learn that the now extinct Neanderthal Man had a cranial capacity (brain size) greater than that of modern man. One might explain the vast difference between Man and his rivals on the ground that he was the possessor of an immortal soul or divine spirit. Leaving this rather unsatisfactory explanation aside, let us try to find some other approach. The key lies in the capacity of humans for abstract thought—taking a step back in their minds and introspecting with this marvellous faculty comes natural talent to convert the results of these introspections into a code and communicate them to other members of the species. The communicating code is what we call language and the introspective process, with or without a linguistic component, is known as thinking. Thinking of a kind probably comes in a good deal lower down at the level where individual animals make decisions, such as when a dog faced with a fence blocking it from its food ultimately gives up trying to climb over it and simply walks round it. Kohler's chimpanzee Sultan was certainly indulging in something pretty close to thought when he fitted two

sticks together to reach a banana. Nevertheless there is rather good evidence that the development of a spoken language such as only humans have is the trigger which allows a kind of detached abstract processing to go on and which has allowed us to build up an immense cultural heritage over the past 10 000 years.

(a) Thought and Language

How much is thought tied in with speech? You will remember that Watson liked to call thought sub-verbal speech and there is some truth in this. Open your mouth and think the word bubble. You will probably notice a kind of catch in your throat—which shows how the two processes are tied together. On the other hand think of some visual scene—say a polar bear sitting on an iceberg. Most people can conjure up a pretty reasonable mental picture of scenes like this without too much trouble and certainly without saying vocally or sub-vocally either the word bear or iceberg! Incidentally if you can't get a mental image of this kind don't worry for about a third of the world's population can't either. This facility for producing pictures in the mind has puzzled psychologists for a century—in particular those who can't manage the images themselves who are inclined to be a bit sceptical about the whole thing. Twist the topic round and consider the case of visual illusions and other perceptual anomalies. For example take the kind where two lines objectively the same look to be of different length. No matter how much measuring with a ruler and how much you tell yourself that the lines are similar your erroneous percept remains. Here perception and thought are *not* inextricably tied which disposes of any lingering arguments that thinking was merely a consequence of visual, auditory or some other input. Incidentally the link between thought and language is suddenly coming under close study again almost 50 years after Watson had originally tried to explain one in terms of the other. This arises from the young sub-science known as psycholinguistics the founder of which is the American mathematician, Noam Chomsky. His thesis rather seriously oversimplified is that the structure of language can be used to give us a valuable key to the inner logic of the brain's operation. We can never hope to know directly how the inner mechanics of the brain work, so we must look to find them reflected in some more directly observable process. Chomsky and his followers argue that in addition to its surface grammar (the kind of grammar we learn at school) all human languages have a deeper set of rules closely tied in with the programmes which handle the deepest and most fundamental thought processes. Look closely at language state and define the logic of the deep grammar and you have taken a peek at the brain's deepest secrets. It is an interesting idea, shared by many scientists who hold that similar clues can come from a study of dreams, but it suggests that the problem of defining thinking is even harder than we at first imagined.

(b) Can a Machine Think?

Yet another approach comes from computer scientists, who concerned with devising computers capable of communicating in linguistic terms with human beings have been taking a close look at these problems. From one of the pioneers of computer science the late Alan Turing of Manchester came a penetrating analysis of the philosophical problems of thought which reopens the discussion again from an entirely fresh angle. He did this by posing the question: Can a machine think? Turing pointed out that the almost universal response to this question was 'No' but while people felt pretty confident in their opinion, they were seldom able to give a really good reason for it. Typical responses when they were asked why a machine couldn't think included, 'because you can never get more out of a machine than you put into it' because machines have no souls, and 'because only people can think. None of these arguments is valid. In the first place it is only partly true to

say that you can get no more out of a machine than you put in it and in any case what has that to do with thinking? The second and third points are equally dubious. However, Turing realised that people had a built-in inclination to assume that thinking was a property of humans only and as a computer engineer who hoped ultimately to see thinking computers developed he was anxious to correct this impression. To do so he rephrased the question this way:

Supposing that you continually built ever more clever computers: how would you know whether one had begun to think or not? Pointing out that the only evidence we have about whether humans can think (apart from taking their word for it) is the nature of the conversation they have with us he suggested that one would base one's decision on how well the computer was able to communicate and discourse. Assuming that the fact that the computer was a large metal object with glowing lights, reams of paper tape etc. would bias people in their judgment of whether it was thinking or not, he proposed that the decision should be based on a simple game. Take one very clever computer which you have reason to suppose may be capable of thought and place it in a room A. Now take a person in a room B and a third in a room C. Connect up computer A and person B to person

C by wires connected to teletypes (special typewriters which allow one to feed information into computers and allow them to respond). Person C doesn't know who is on the end of either teletype B or the computer, but he proceeds to try to find out by asking them questions through their respective teletypes. Now if the computer was really *thinking* it would soon give itself away by its *fun* answers, but if it was really clever it might easily fool C into thinking it was the person B. One important rule of the game incidentally is that both B and the computer were attempting to fool C: the object being not to be identified correctly as either human or machine. Now said Turing: if the point comes where C cannot reliably and certainly decide which of his two communicators is which then to all intents and purposes the computer A must be said to be capable of thought! This is really a brilliant approach to the problem even if it seems to be a bit obscure at first. What Turing was really saying was that the *real* evidence that thinking is taking place is evidenced by what the individual, be it human, animal or computer actually does and not what it looks like. (Hence the separation of the three beings in the above guessing game into separate rooms and the elimination of such relatively irrelevant variables as sight and sound.) Can people would agree that his tool making activities were evidence of at least rudimentary thought processes. This evidence as we have said is based on what the creature did—not what he looked like or whatever prior prejudices one had about apes thinking.

Before leaving this enigmatic topic consider two recent developments in this area:

(1) A pair of American psychologists husband and wife reared a young chimpanzee from birth alongside their new born son treating the ape as one of the family and rearing it in precisely the same way as they did the child. For the first two years the chimpanzee matured far more rapidly than did the human child but after the age of two with the acquisition of speech the young boy surged ahead. In its last desperate attempts to keep pace however the chimpanzee began to make primitive speech sounds including the enunciation of words like cup and water when it wanted a drink.

(2) In a computer complex in Boston where a number of scientists are connected to a central computer and also to each other via teletypes, two researchers were conversing with each other via the system. The computer was also present as a third person assisting them with their calculations. One of the scientists got up to leave the room without telling his friend who continued conversing quite happily with the computer. Only when the first scientist returned was the unique dialogue between man and computer dis-

rupted. Had the machine passed Turing's test? There are scientists today who argue that it had and while there are plenty who disagree quite the majority of computer engineers hold that it will not be long before their charges are capable of clearly demonstrating their capacity to think and not merely to compute.

(5) The World of Inner Space

We have constantly indicated that psychology is the study of behaviour—the activities of living creatures which respond to a meaningful non-random way to the vagaries of their environment. The key to understanding these patterns of behaviour is of course the brain and within the brain itself the programmes which control and determine its actions. One important point which all who study the brain swiftly come to realise and one which this section has attempted to emphasise is that no living system can be considered as a mechanical assembly of different parts. Each whether carving out or human being is a complex integrated system functioning as a unit. The further up the phylogenetic scale one rises the more complex the system and the more sophisticated and elegant its mechanics. At the human level with mental activities and consciousness emerging as super control systems the study of psychology reaches its most fascinating point. Here too it must be admitted as a science it has made least headway. There are probably good reasons for this some related to the intrinsically complicated nature of the mind others to the attitude of the psychologists themselves. The early pioneering work of Wundt, Ebbinghaus and others seemed to be setting psychology on course as a science in its own right. The work of Pavlov immensely important and relevant as it was served to weaken psychology as a discipline and shift its bias drastically in the direction of physiology. Psychologists themselves ceased to think like psychologists and instead attempted to convert themselves into second hand physiologists part time and mathematicians and indifferent clinicians. This trend which gathered strength in the 1930s has persisted until quite recently when a growing disenchantment with the relatively meagre results stemming from the millions of behaviouristic experiments involving pigeons, monkeys and rats has led to an inevitable swing of the pendulum. More now than at any time in this century is the primate creature for psychological study acknowledged to be man himself. Also for the first time since the turn of the century man is ceasing to be a dirty word to psychologists. Freud's fabulous and enduring insight—that the mind itself had two vitally important parts: the conscious and the unconscious each integrated and yet strangely autonomous—was being treated with ever greater respect and understanding today. The realisation that human beings are controlled not merely by their conscious thoughts wishes and desires but also by dynamic forces of great power which are *not* under conscious control and barely available to linguistic analysis is at last becoming a part of even the layman's view of mental life. The tip of the iceberg above the sea as Freud pointed out is that part of the mind which is under conscious control. Below the sea, massively enigmatic, lies the great bulk of the unconscious repository of the programmes which largely determine the behaviour of man. This is the zone rich in mystery which must ultimately be plotted by psychology and its researchers. This is the territory glimpses of which we catch through the enigma of memory, the hallucinations of dementia, and in the misty drama of our dreams. The controversial English author J. G. Ballard has christened this territory *inner space* in contrast with the vast reaches of outer space that the first human astronauts are today beginning to explore. The explorers of inner space are psychologists, their colleagues in similar disciplines and all who journey along with them. At this stage their voyage has barely begun and as with the astronauts has no foreseeable ending. One thing is certain—it will be no less fascinating and no less rewarding. On the one path man seeks to discover his universe on the other to discover himself.

MODERN GARDENING

A guide for the gardener on all
aspects of horticulture particularly
in the control of pests and diseases
and the eradication of weeds by the
latest means

MODERN GARDENING

CULTIVATION OF FLOWERS

Throughout this section the notes must be taken to refer to cultural conditions in the British Isles although in many cases the information can be adopted to suit the necessity of readers living abroad. Undoubtedly in many temperate parts of the world interest in gardening has increased enormously during the past decade or so despite the fact that numbers of large gardens have ceased to exist and that few people can afford to pay for full time help in their gardens. To counteract this the all important labour saving garden has come into its own. Shrubby plants have replaced annual bedding schemes and large lawns put down instead of herbaceous borders or beds of particular plants.

In addition, the owner gardener is anxious to avail himself of the excellent selection of modern tools thus the conventional hoe is being replaced by the Swoc or the Wolf pattern of Dutch weeder both of which are very easy to use and digging can be done quickly—and with much less effort—by using a German digger called a Terrex spade. For grass mowing the work is easily done with motor mowers like any of the new battery driven patterns.

For greenhouse work, smaller houses are being used and one say 12 ft. by 8 ft. can be run economically with a minimum winter temperature of 40° Fahrenheit by the introduction of trouble-free thermostatic heaters or the turbo-heaters. At the moment besides automatic heating the prototypes for automatic ventilation and watering are making an appearance.

While advocating the use of such appliances it must be pointed out that there are also to be found tools sundries and fertilisers of little value and many of which have never been properly tested prior to being put on the market. It is therefore a good plan to discuss the comparative merits of any appliance or horticultural sundry with a competent horticulturist or to contact a public authority. In particular many local horticultural societies have special trading facilities and the merits of most garden things are generally known and discussed among members.

Throughout this Guide the vexed question of change in scientific name has been dealt with as liberally as possible and whenever necessary synonyms and cross references are given. In dealing with cultivar names that is, varietal names like rose Peace reference is made as recommended in the *International Code of Nomenclature for Cultivated Plants* (1957). By so doing the references are right up to date and further information on any particular plant or subject is easy to find. For the purpose a few standard works of reference are given after each section. Normally all the plants mentioned in the text are available through the usual trade channels.

After each plant listed there is a note on its propagation. Generally this is the easiest or most efficient way of doing so but it is not necessarily the only means. Details of the various methods employed are as follows.

Seed. Generally speaking the early spring is the most suitable time for sowing seeds of trees and shrubs besides those of herbaceous plants and alpines. Where only a few plants are needed the seed can be sown in pots and a suitable compost made up with 2 parts of soil, 1 part of peat and 1 part of coarse sand. Before sowing the pot should be stood up to its rim in water so that the soil is soaked. Then the seed can be sown thinly and covered with a light sprinkling of sifted compost.

For very fine seed like begonias or azaleas, the seed must have only the merest sugaring of sand just sufficient to anchor it. When sown, the pots should be covered with a pane

of glass (to prevent evaporation) and kept, if possible in a warm greenhouse or frame. With this method of propagation it is important to remember that failure will result if the seed is sown too deeply if the temperature is too low or if the soil is too dry.

CORRECT PREPARATION OF SEED POTS AND PANS.—Note provision for ample drainage and compost to rim of its container. After sowing the containers are covered with a sheet of glass.

Cuttings. There are two main types of cutting—soft wood cuttings made from fresh green shoots in the spring and summer and hard wood cuttings made of mature or semi mature woody shoots in the autumn. A soft cutting is taken about 3 in. long the lower leaves removed and a clean cut made through a node in the stem. These are then inserted in pots containing a light sandy soil or a rooting medium such as horticultural vermiculite well watered and covered with a bell jar or plastic bag. Delphiniums, hydrangeas and lupins are all propagated in this way.

Hard wood cuttings are taken in the autumn and made from shoots about 8-12 in. long. These are inserted in a sandy soil out of doors or in a cold frame and left to develop for a year. Black currants, forsythia and roses can be propagated by this means.

Layering. This is one of the easiest ways of propagating the majority of woody plants, and is used to increase stocks of plants like Clematis, lilacs and rhododendrons. Normally layering is done in the autumn or spring when suitable branches are pegged down. On each of these the young shoots are in turn, pegged down and then turned upwards and tied in position. To encourage rooting gritty sand and peat should be worked around each layer and usually the young plant can be severed from the parent after about eighteen months.

Division. By this method it is easy to propagate the majority of herbaceous plants, some rock garden plants and a few shrubs. A few herbaceous plants, like delphinium and peony, are slow to get established after moving, and here the method should not be employed. In any case old plants should not be split up in a wholesale manner. Instead, it is far better to select a few young healthy plants divide these, and replant the best of the young shoots in the autumn.

ALPHABETICAL LIST OF ORNAMENTAL PLANTS

Abutilon.—The greenhouse species is often used in public parks for bedding schemes. *A. vitifolium* with white, mauve or blue flowers makes a fine wall shrub for warm gardens. If given full sun it will quickly reach 10-15 ft., but is sometimes short-lived. **Prop.**—Easily raised from seed sown in March in a warm greenhouse or frame.

Acer (Maple)—Hardy ornamental trees the Norway maple is often planted for its magnificent autumn colour and as a lawn tree. *A. palmatum* and vars constitute the Japanese maples all colour brilliantly in the autumn but do not grow freely unless given some shade and a light soil rich in humus. *Prop*—Seed layering or budding.

Achillea (Yarrow)—Grey leaved perennials for open border or dwarf species for rock garden. Valued as a cut flower particularly *A. ptarmica* Perry's White with double white flowers and *A. eupatorioides* Gold Plate with large flat yellow flower heads. *A. millefolium* is a pernicious weed of turf (T34). *Prop*—Division in autumn.

Acanthaster—Scented bulbous plant introduced from Abyssinia. It is not difficult to grow if the corms are planted in the spring and lifted in the autumn for storing in a frost proof shed. It requires a sunny position and plenty of water in the summer. *Prop*—Offsets removed when the old crop of bulbs is lifted.

Aconitum (Monkshood)—Blue flowered perennial plants particularly useful for lightly shaded positions or full sun. flowers from May to July height 3-5 ft. roots poisonous. *Prop*—Seed or division.

Adiantum—See Ferns

A WELL-GROWN AGAPANTHUS—In winter the pot should be kept in a cold greenhouse or some protected place in summer afforded full sun.

Agapanthus—A bulbous plant native of South Africa usually found in seaside gardens and some times grown in tubs. flowers blue violet or white. It needs winter protection in the form of a covering of bracken or straw and a light soil heavily enriched with manure. Worthy of wider cultivation. *Prop*—Seed or division in March.

Ageratum—Blue flowered carpeting plant. See Annuals.

Allium (Flowering Onion)—A genus of nearly 300 species of bulbous plants widely distributed over the Northern Hemisphere. The foliage has the distinctive smell of garlic but some species are grown for garden ornamentation. In particular *A. roseum* valuable late flowering rock plant for dry positions. *Prop*—Offsets taken from parent bulbs in the spring.

Astroemeria aurantiaca (Peruvian Lily)—This tuberous-rooted, herbaceous plant is often grown for cutting. Flowers orange red and height 2-3 ft. of easy culture if afforded a sunny position and left undisturbed. For best results apply liquid manure or soft water when growth starts. *Prop*—Seed or division.

Althaea (Hollyhock)—A truly delightful, old world plant but not often seen as modern hybrids

have given way to rust disease. Best grown in a rich heavy loam. Much with maturing of any sort and stake as necessary. *Prop*—Seed in June thin out and transfer to flowering position in September. Although a perennial in some localities the best results are obtained by treating it as a biennial and raising a small supply annually.

Alyssum—Low growing annuals and perennials for rock garden and sunny border. The perennial *A. saxatile* is deservedly popular by reason of its bright spring flowers and value as a wall plant. The variety *Ostrinum* is bright yellow and Dudley Neville hascut yellow. *Prop*—Perennial sorts by cuttings in June.

Amaryllis belladonna—Often this plant is confused with the greenhouse bulbous plant *Hypocastrium*. The true *Amaryllis* is a half hardy bulb for planting at the foot of a warm wall. It has white to pinkish red flowers. When planting cover neck of bulb with an inch of soil and leave undisturbed, as the plant resents moving and is slow to get established. Lack of flowering is generally due to planting too deep. Established clumps may be fed with hoof and horn meal at 2 oz per sq yd in July. *Prop*—Divide and replant clumps in early July.

Amelanchier canadensis—A large shrub or small tree valuable for its spring flowers and autumn colour. As it will grow almost anywhere in sun or shade it makes a good plant for informal screening. *Prop*—Seed or layers.

Ampelopsis—See *Parthenocissus*

Anchusa italica—A blue flowered perennial with fleshy roots growing to a height of about 3 ft. Responds to feeding and needs a position in full sun. *Prop*—Root cuttings in the spring divide on in the autumn.

Anemone—The tuberous rooted section includes the Caen and St. Bridget strains. These are best grown in an open position in light rich soil. plant in October lift and store when foliage dies. The hardy fibrous rooted perennials are varieties of *A. hybrida* (syn *japonica*) and constitute one of the most accommodating of perennials being particularly useful for damp shady positions. Worthy of wider attention from gardeners. *Prop*—Perennial sorts by division in autumn.

Annuals—These are plants which develop from seed flower fruit and die within a year. Additionally some perennials like *Antirrhinum* may be treated as annuals for the convenience of their cultivation. Sunny borders may be planted solely with annuals they may be interplanted with perennials, used for window boxes or occasionally in the rock garden. All sorts do best in well worked light loam enriched each year with a dressing of fish meal at 3 oz per sq yd ten days before sowing or planting.

In the division of the group Hardy Annuals may be sown in the open ground as soon as conditions permit during March or April where the plants are to flower. Wet or cold soils will give many failures and fine seed should be covered only with the lightest sugaring of soil. Often surprising—but delightful—results may be obtained by sowing broadcast mixed seed of annuals specially offered by some trade houses.

To raise Half Hardy Annuals seed may be sown in early March in a warm greenhouse and the seedlings pricked out into boxes. Subsequently the plants are grown on in a cold frame gradually hardened off and then transferred to their flowering positions towards the end of May.

Antemiss tinctoria—Hardy perennial with feathery grey foliage and flowers in varying shades of yellow. Height 2-3 ft. needs full sun and good for cutting. *Prop*—Division in the autumn. *Antemiss nobilis* is the chamomile sometimes unwisely used to make lawns.

Antirrhinum (Snapdragon)—The popular bedding plant requiring a good soil and position in full sun now largely in disfavour owing to rust

disease planting should be restricted to rust resistant varieties. *See Annuals*

Apheleandra squarrosa.—An evergreen, perennial plant introduced from Brazil. Often sold as a house plant, albeit a warm temperature and a high humidity are necessary for its cultivation. When grown indoors it is best discarded when the flowers fade and the foliage starts to wither as it cannot be successfully grown on from year to year under normal conditions indoors.

Aquilegia.—The modern race of hybrids are the result of much interbreeding with wild forms to give a wide range of colours. Best when planted in light shade where soil is naturally moist. *Prop*.—Seed in late spring. Transplant to flower ing position for following year.

Arabis caucasea.—Once known as *A. alba* this common rock plant is often used on dry walls. The double flowered form is particularly good. *Prop*.—Cuttings in July. A fresh stock should be raised regularly as the special forms tend to die out.

Araucaria (Monkey Puzzle).—This tree was introduced from Chile where it forms large natural forests and widely planted in Victorian days. Browning of foliage suggests lack of water in the summer or occasionally effects of very cold weather. It should be planted in a position protected from the prevailing wind. *Prop*.—Seed in a warm greenhouse.

Armeria maritima.—A hardy perennial with pink or red flowers in the spring. Must be grown in full sun where the soil is dry. *Prop*.—Division after flowering.

Artemisia.—A genus of shrubs and perennials suitable for sunny borders or rockeries. *A. lachniflora* is among the best of the herbaceous species having grey foliage and creamy white flowers. *A. abrotanum* (daisy love) in the shrubby section has grey fragrant foliage. *Prop*.—Herbaceous section by division. Shrubs by cuttings in the early summer.

Arundinaria.—*See Bamboo*

Aster (Michaelmas Daisy).—By careful breeding this plant has been improved out of all recognition, and many first-class varieties are available in the trade. Responsive to good cultivation, it is used for its colour late in season and properties as a cut flower particularly *A. yunnanensis* Napbury and *A. Barr's Pink*. A wide range of colours are available besides some fine, low-growing forms. In the border one pleasing combination can be made with *A. Harrington's Pink* and *Scabious Dinkie*. *Prop*.—The clumps should be split up annually in the spring and only the plumpest pieces of outer root replanted.

Aster China or Common.—*See Callistephus*

Astilbe.—Allied to the *Syringa* and useful for planting in moist rich soils. Flowers white, pink, and crimson. Height 2 ft. *Prop*.—Division of clumps.

Aubrieta.—A name often misspelt. Throughout the country it is used as edging or for dry walls. Many lovely sorts available apart from the commonly found pale blue variety. It is a lime lover. *Prop*.—After flowering the plants should be severely trimmed and as necessary stock increased by division.

Aucuba japonica.—Much maligned and overplanted shrub but one tolerant of neglect and sunless or smoky conditions. Interesting variants of the type like *Crotonifolia*, may be found in trade lists. *Prop*.—Cuttings rooted in the open in July.

Auricula.—Correctly known botanically as *Primula auricula*. Flowers of alpine auriculas are white or yellow while in those of florist auriculas are to be found some of the most delicate colourings among hardy plants. Choice varieties are grown in pots under glass. Others in most

shady borders. *Prop*.—Seed or division in the spring.

Azalea.—*See Rhododendron*.

Bamboo.—The common name for the large group of woody grasses reference to which is difficult owing to the confusion in their nomenclature. Often grown for screening and wind breaks and is a favourite shelter for small birds, the best for home grown canes are *Phyllostachys viridis* and *Sinarundinaria nuda*. An interesting account of bamboo growing is found in the *Four Roy Hort. Soc.* (June 1937). Growth can be encouraged by feeding with sulphate of ammonia and mulching with leaf mould in the spring. *Prop*.—Division of clumps in late spring. Transplant must be kept watered until established.

Begonia.—A genus showing wide diversity of form and much horticultural value. Of particular interest is the tuberous rooted section of which many of the loveliest varieties have originated in the nurseries of Messrs. Blackmore and Landor at Bath. For bedding schemes the tubers are started in boxes of rich soil under glass in late March and planted out 9 in. apart in June. During the summer feed with liquid manure of any sort and keep moist in dry periods. *Prop*.—Cuttings in early spring in a warm case.

Berberis.—An extensive genus of beautiful and easily grown shrubs evergreen and deciduous, the former used mainly for beauty of flower and the latter for autumn colouring and ornamental fruit. *B. schenophylla* makes a fine evergreen hedge invaluable for preventing illicit entry by dogs and even unruly children. *B. aggregata* and *B. yanceana* are among the best berrying kinds. Prune in the winter by removing old wood. *Prop*.—Seed in spring or layering in autumn.

Buddleia.—Deciduous shrubs of easy culture for sunny positions. Varieties of *B. davidii* available in range of colours from purple to white best when pruned hard by cutting all previous year's growth back to main stems in February. The weeping species *B. alternifolia*, often grown as a standard, good specimens at R. H. S. Gardens Wisley. This sort must be pruned in the summer by cutting off the dead flowering stems. *Prop*.—Cuttings in July—August in cold frame.

Cactus.—In the main grown in cool greenhouses or as house plants and if cultivated well many will flower every year. As a general guide plants should be watered fairly freely in the summer and little in the winter but there are exceptions. A detailed account of growing these fascinating plants will be found in *The Cactus Grower's Guide* by Vera Higgins (Latimer House) 1946.

Calceolaria.—Seed of the greenhouse biennials sown in June or July for flowering in the following year. Mixed seed provides a wide range of colour. *C. integerrima* is a half hardy perennial raised by cuttings or seed, for greenhouse or bedding work.

Calendula (Marigold).—This common hardy annual is freely raised from seed sown in August. Of easy culture in any sort of soil, although it is worth getting seed of new varieties now available. *See Annuals*.

Callistephus.—The China asters are among the best half-hardy annuals for garden and indoor decoration, but good soil and full sun are necessary for best results. *See Annuals*.

Camellia japonica.—Hardy evergreen shrub rightly beloved by connoisseurs and cultivated in gardens for many centuries. May be grown in cold greenhouses, woodland gardens, and against north and west-facing walls under all conditions. Camellias must have a moist acid soil. Best varieties for outdoors are *Althaeiflora* (dark red), *Donckelarii* (red, white marbling) and *O. M. Wilson* (pink). Of recent introduction is the desirable *C. sutchuanensis* bred from *C. japonica* in part. Often the subject of television and gardening notes. The dropping of buds is thought due to dryness at the roots at some time

or sharp fluctuation in temperature *Prop*—Named varieties by cuttings under glass in early July. Otherwise plants easily raised from seeds if sown in the autumn immediately they are ripe in acidic peat and kept moist.

Campsis grandiflora—Sometimes found listed as *Bignonia* or *Tecoma* choice deciduous climber for warm wall large reddish orange flowers in autumn. To encourage flowering growth prune hard back to old growth in spring *Prop*—Cuttings in April struck in a warm case.

Canary Creeper—*See Tropaeolum*.

Candytuft—Hardy annual (*qv*) and perennials with white crimson blue or purple flowers. The perennial—*Iberis sempervirens*—is a fine plant for a rock wall *Prop*—Seed or perennials from cuttings.

Carnation—*See Dianthus*.

Centaurea (Cornflower)—The perennial species are valuable for cutting and border use and may be found in such colours as pink, crimson and yellow *Prop*—Lift and divide every third or fourth year. The hardy annual *C. cyanus* is often sold as a cut flower *See Annuals*.

Chaenomeles speciosa—This is the correct botanical name for *Japonica*. The species commonly grown is a wide-spreading rounded shrub 6-10 ft. in height and often used against walls. It is a plant of easy culture with best results being achieved by the annual spurring back of the current season's growth in the same way as an apple tree is pruned. All *Japonicas* can be used for making jelly but for this purpose the best one is *Chaenomeles cathayensis* a gaunt shrub about 10 ft. in height which bears fruit up to 8 oz. in weight. To obtain a crop within a reasonable time two or three plants may be set in a group about 5 ft. apart. If growth or flowering is below par all *Japonicas* should be fed with Growmore and mulched with compost.

Cheiranthus cheiri (Wallflower)—Among the finest displays of this biennial are those found each year in the public gardens of Southend on Sea, where it is used in conjunction with bulbs and forget-me-nots *Prop*—Seed sown thinly in rows in May and seedlings thinned or lined out and then transplanted in late autumn. The so-called Siberian wallflower *Erysimum asperum* which has bright orange flowers is grown in the same way but it is intolerant of wet soils. Both sorts are lime lovers and on acid soils plants may receive treatment with 1 oz. of lime in a gallon of water.

Chimonanthus (Winter Sweet)—Hardy winter flowering shrub with heavily scented flowers. Although brought to this country from the Far East in the mid eighteenth century its garden value is not widely appreciated. The large flowered yellow sort *C. praecox* is particularly fine but like all the varieties it is best grown against a sunny wall and where the soil tends to be poor. If growth is excessive and flowering poor trim back young growth severely in March to encourage short spur like shoots *Prop*—Easily raised from seed or layers.

Christmas Rose—*See Helleborus*.

Chrysanthemum.—Hardy annual sorts are available in a wide range of colours and give a fine display in the summer months *See Annuals*. There are also a number of perennials such as the shaft daisy and the oxeye daisy for sunny herbaceous borders all do well in ordinary soil, but should be lifted and split up about every three years. The plant sold by florists in the autumn is the Japanese *chrysanthemum*. Many are hardy out of doors, but no plant is more responsive to good cultivation and normally is best left to the specialist grower. For ordinary garden work, the best sorts are the Korean and Olney types. Under a brief reference the interesting details of cultivation cannot be dealt with fairly and reference to specialist books is recommended.

Clematis.—A hardy climber for walls screens pergolas and the like. Best kinds are to be found among named varieties in nurseries like *A. light* well drained soil is necessary and if fed annually with a bucketful of manure or compost the plant will thrive for many years. Occasionally plants will be found on north wall and if grown in full sun some light protection from the sun is desirable for the roots. Varieties which flower on the current season's growth like *C. Jackmanni* should be pruned in late February to within a foot of the ground other sorts should have sufficient old growth removed after flowering to keep them within bounds.

Sometimes the climber is killed by clematis wilt so premature death of young plants should not be automatically blamed on the supplier. Control is by spraying with a copper containing fungicide *Prop*—Layering by which means one shoot will often give three or four plants.

Convallaria majalis (Lily of the Valley).—Well known perennial that will thrive in any damp shady position. For best results lift every four or five years and mulch annually with old manure *Prop*—Division when foliage fades.

Coreopsis.—The hardy annuals are found in catalogues under *Callipais* and all will thrive in ordinary soil. The flowers are mainly bright yellow and many are good for cutting *See Annuals*. Similarly the perennials have the same predominant colour and are useful because of their long flowering season and abundance of flower *Prop*—Division.

Cornflower—*See Centaurea*.

Cosmos.—Tall growing half hardy annuals that are best grown in full sun in a dryish border. The large daisy like flowers can be had in a variety of colours including white yellow pink, and crimson *See Annuals*.

Cotoneaster.—Hardy evergreen and deciduous shrubs or small trees bearing scarlet or sometimes yellow berries in the autumn. All may be grown in ordinary or poor soil and planted in open or shady shrubberies and trailing species used against walls over banks or as ground cover. For shrub berries *C. lacteus* and *C. Cornubia* with red berries and *C. rostrichiduanus* with yellow berries are among the best sorts *C. conspicuus* Decora is a strong grower for banks while *C. horizontalis* is an excellent cover for any wall. Planting may be done in the autumn or spring and no pruning apart from occasional shaping is required *Prop*—Seeds and layering.

Crataegus (Hawthorn).—There are many good varieties of our British hawthorn *C. oxyacantha*, worthy of attention particularly *Coccinea* (crimson) and *Pauli* (double red). All will do well on poor soils and no pruning is required. The common hawthorn makes a stout impenetrable hedge planted 9 in. apart in a double row 9 in. asunder *Prop*—Common sort by seed choice varieties by budding.

Crocus.—A hardy bulb of great beauty which was studied for many years by one of the best horticulturists of the twentieth century the late E. A. Bowles. Does best in rich soil planted in bold groups around margins of beds or borders and naturalised in grass. When required feed in early spring with bone meal at 2 oz. per sq. yd. *C. sieberi* and *C. tommasinianus* flower very early the large flowered garden forms about three weeks later. *C. zonatus* flowers in the autumn and is often naturalised in grass *Prop*—Clumps may be lifted and divided about every five years in July. The so-called autumn crocus is *Colchicum autumnale*. This bears large lustrous leaves in the summer followed by mauve or white flowers—of fleeting duration—in the autumn.

Crown Imperial.—*See Fritillaria*.

Cytisus (Broom).—Only does really well in dry poor soils in full sun. choice procumbent sorts like *C. kewensis* used in rock gardens and tall ones

in open shrubberies. Pruning is important; shoots should be shortened after flowering, but old wood must never be cut. *Prop*—Seed and cuttings in August in a sandy soil.

Daffodil—*See Narcissus*

Dahlia—The cultivation of this plant is a special study, and there are probably more garden varieties of it than any other plant. Ordinary soil enriched with manure and an open position is required. Tubers may be planted 3 in. deep in April or young plants in late May. During the summer feed with soot water and liquid manure. After the first frosts lift dry and then store tubers in peat or straw in frost proof place. Many stocks of dahlia are affected by virus (T30) and purchasers should be careful to check source of supply.

Daphne—Shrubby plants giving some of the most richly scented of all flowers. In particular there is *D. mezereum* which requires a damp soil; failure with the shrub is due usually to root disturbance or virus disease (T31). *D. odora* is one of the evergreen fragrant species. Some references have suggested that this lovely shrub is not hardy, but there is no evidence to support the supposition. *Prop*—Seed or layering.

Delphinium—Hardy annuals and perennials. The latter sorts have gained popularity enormously since the War, due in the main to the activities of the Delphinium Society, but also to the introduction of many very fine new varieties. American hybrids like the 'Pacific Star' are very large but tend to die out and consequently lack the true perennial habit of European sorts, albeit some of these have been weakened by the introduction of poor lines. It is important therefore to select stocks of strong constitution. Delphiniums need a deep rich soil and a sunny position protected from wind. Plant in autumn 3 ft. apart, feed in the summer with liquid soot water and mulch with decayed compost or manure in the spring. When growth starts thin out weak growths to leave not more than five stems per plant. In winter take steps against possible slug damage (T26) and on this point it is beneficial to protect crowns with a covering of ashes. *Prop*—Cuttings in the spring or seed division of clumps is a poor alternative.

The hardy annual sorts are the well known larkspurs which grow to a height of 18 in. to 2 ft. and may be found in a range of colours including pink, red, white and shades of blue. *See Annuals*.

Deutzia—Hardy deciduous shrubs thriving in any soil and valuable for their summer flowers of white or whitish pink shade. To keep the plants vigorous shoots should be shortened after flowering and old or weak wood cut out. *D. scabra* is of robust habit reaching about 7 ft. and *D. elegantissima* fasciculata proves a graceful shrub some 5 ft. tall with clusters of about twenty flowers coloured rosy pink and each nearly an inch across. *Prop*—Cuttings made from firm young growths about 10 in. long in sandy soil out of doors.

Dianthus—This name covers a wide range of annual, biennial and perennial plants. At one time often grown for their fragrance but to a large extent this has been lost with the introduction of wider ranges of colour. Border carnations and picotees grown out-of-doors need a limy fairly rich soil in full sun. Plant in the autumn or spring and as the buds appear feed with soot water or liquid animal manure, if necessary. These groups are not of good perennial habit and should be propagated annually to ensure continuation of stock.

The common pink requires the same soil conditions and should be propagated when the stock gets weak. Good scented varieties should be sought and include the Imperial Pinks, Mrs. Simkins and White Ladies. *Prop*—The best method is by layering in July so that the new plants can be put in their flowering position by mid-September. The lower leaves are pulled off selected shoots and a slit passing through a joint is made in the stem. Each layer is then pegged down with a hair pin, the pin being placed above the cut. The layers are then covered with an inch of sandy compost and well watered.

In this genus is the sweet willow, although truly a perennial it is generally grown as a biennial and consequently the plant is raised from seed in May out of doors. In gardens where it is prone to rust disease control is most difficult and it is not worth a place.

LAYERING CARNATIONS—This is a typical example of how many plants can be propagated. A strong new growth is pegged down into sandy soil after a cut has been made in the stem, at the point of pegging. Once rooted the layer can be severed from the parent and transplanted a week or two later.

Digitalis—The biennial sort generally found in gardens is the common foxglove which is grown in light shade in fairly rich, moist soil. In the past many named forms have been offered in the trade but undoubtedly the best one is *D. Sutton's Excelsior*. *Prop*—Seed sown in May out of doors.

Doronicum—Hardy perennials with yellow flowers warrants wider planting as they are among the earliest perennials to bloom and will thrive in poor soil or in some shade. The best is *D. austracum* flowering in March, height 9 in. *Prop*—Division after flowering.

Echinops—Name appropriately derived from *echinos* a hedgehog in reference to the spiny long scales of the flowers. The plant does well in an open position, where the globular heads of steely blue flowers can be seen to advantage. *Prop*—Division in March, but best left undisturbed as long as possible as it must be moved with care.

Elaeagnus—Hardy deciduous and evergreen shrubs generally grown in rather dry positions as foliage plants. Of the evergreen sort *E. pungens* 'Aureo Variegata' has bright golden variegation and is therefore valuable for indoor decoration during the winter. *Prop*—Layering in late summer.

Erica—The heathers are native plants to Britain, and many variants found in the wild have been introduced into gardens to good purpose. Indeed, heathers have become so popular that special Heather Gardens have been made, and two fine examples may be found in the Royal Gardens Windsor where the planting is new and the Royal Horticultural Society's Gardens, Wisley. Here, different sorts reaching the dimensions of small trees dwarf kinds, and many scores of interesting variants, to supply flower throughout the year will be found.

The Scottish heather is botanically *Calluna vulgaris* and, like all British heathers, it is intolerant of lime or chalk. Where alkaline conditions exist planters can try *E. carnea*—a winter flowering heather—or *E. darleyensis* but the results are usually disappointing. When planting all heathers clumps must be well firmed and after

wards kept moist subsequently mulch all types annually with peat *Prop*—Division and layering

Erigeron—Hardy perennial for sunny borders daisy like flowers freely develop and are good for cutting *Prop*—Division in the autumn

Escallonia—Slightly tender evergreen and deciduous shrubs In the Midlands protection of a south wall is necessary suitable for open shrubbery in the South Ideal for maritime conditions and here may be used to good effect as hedge. Many of the best varieties originated in the nursery of Messrs The Sheve Donard Co in County Down *Prop*—Cuttings under a glass jar in summer layers in September

Eschscholzia californica.—A hardy annual of any culture height 18 in flowers in many shades of orange *See* Annuals

Everlasting Flowers—*See* Helichrysum.

Ferns—A large number of plants are included under this name and as they grow wild in many parts of the world some need lathouse conditions They are distinguished from flowering plants by their method of reproduction instead of producing seeds ferns develop spores usually on the back of their leaves The hardy kinds may be grown in equal parts of leaf mould and soil and the fronds of leaf losing kinds should not be removed until the spring as they offer some protection from the cold Tender ferns should be potted when new growth starts in the spring in a compost of equal parts soil leaf mould and sand using a pot just large enough for the purpose During the growing season, in particular keep the roots moist and plants free from a dry or smoky atmosphere *Prop*—Division of clumps when growth starts in the spring

Forget me nots—*See* Myo idis

Forsythia—Commonly found in many gardens as it is of easy culture in any soil Flowers bright yellow in early spring To keep in good shape prune directly after flowering by cutting out old wood *F. intermedia* Lynwood is upright in growth and *F. suspensa* of weeping habit both types make good wall plants for North aspects *Prop*—Cuttings in the autumn

Foxglove—*See* Digitalis

Fuchsia—Greenhouse bulbous plant and if grown for scent care must be taken to select fragrant varieties Pot in the autumn in a fairly rich compost and keep as cold as possible until growth is seen Then bring into a frost free greenhouse and water freely When flower stems appear feed with liquid manure after flowering gradually dry off until time for repotting Failure almost invariably traced to premature forcing before root growth has been made or growing in excessively high temperature *Prop*—Offsets at potting time

Fritillaria.—The one mainly used in gardens is *F. imperialis* a handsome spring flowering bulb To grow it really well this species must be given a deep rich soil and contrary to some views it is best lifted every year as soon as the foliage fades. If growth is poor or plants do not flower feed when growth starts in the following spring with equal parts of bone meal and superphosphate at 3 oz per sq yd *Prop*—Offsets removed from parent bulb at lifting time The old bulb should then be replanted at once and any offsets lined out in a nursery row

Fuchsia—Greenhouse and tender flowering shrubs The outdoor sorts (of which *F. recurvata* is the best) may be grown in light soil in full sun In the spring prune all growth down to ground level protect if necessary in winter with covering of cut bracken or dry straw Greenhouse varieties are potted firmly before growth starts in the spring and when buds burst all the previous year's growth can be cut back hard. To encourage flowering feed with a liquid manure such as dried blood, and syringe foliage in hot weather During the winter keep plants dry and house in a cool

greenhouse *Prop*—Cuttings of new growth taken about 1 in long and inserted in sand under a plastic cover in the spring

Gaillardia—Hardy annual and perennials 18 in to 3 ft high which bear large richly coloured flowers invaluable for cutting in mid and late summer Unfortunately on heavy soil the perennials are liable to die after flowering and even on well drained soils they cannot be considered long lived plants *Prop*—Normally it is necessary to raise a fresh stock in alternate years seed is sown in May in a cold frame and the young plants lined out in a reserve border prior to planting in the autumn

Galanthus (Snowdrop)—Hardy bulbs well worth growing if given a moist shady position where stock can be left undisturbed Planting should be done in fairly bold clumps bulbs are not expensive and many variants like double flowered and tall stemmed ones are well worth trial *Prop*—Lift and divide clumps in August

Gentiana—The gentians comprise some of the most fascinating of all rock garden plants partly perhaps because some are difficult to manage In particular *G. acaulis*—which has true gentian blue flowers—is exacting in its requirements and in many gardens flowering can never be induced What controls flowering has not been discovered and the plant can be grown well in acid or lumpy soils On the other hand *G. ovata* must have an acid soil and is best in a position out of the direct sun Beginners with the genus are advised to start with easily grown sorts like *G. tagoedchina* and *G. epiphylla* *Prop*—Seed sown in cold frame in March or division in early spring

Geranium—The true geranium or cranesbill is a hardy floriferous perennial for rock garden or open border In the latter case *G. ibernicum* (blue flowers) and *G. sinuatum* (Lancashire rosy pink flowers) are exceptionally good and both do well in dry sunny positions The so called bedding or greenhouse geraniums called *pelargonium* (*q.v.*) *Prop*—Seed in March

Glaucolus—Dutch hybridists have done much work on this bulbous plant and many new and lovely varieties are now available The plant is responsive to good cultivation and corns may be planted 4 in deep and 6 in apart during the spring in well prepared ground When the blooms fade remove the dead spikes of flower and lift the corns in September After a month—and this point is important—pull off the old shrivelled corn and clean the new one By doing this there is less likelihood of spores of diseases overwintering on the new stock Finally the corns should be stored in a dry frost free shed, and if given proper attention can be kept for a number of years *Prop*—Bulbs removed when the corns are cleaned can be sown in the spring in nursery rows and will flower within two years

Godetia—Hardy annual of easy culture and tolerant of poor soil conditions and even some shade There are many varieties mainly with bright flowers of rosy pink and crimson *See* Annuals

Guernsey Lily—*See* Nerine.

Gypsophila.—The favourite sort is *G. paniculata* which is often grown for cutting together with its double-flowered form Bristol Fairy To do well gypsophila must be given a dryish soil where the roots can penetrate undisturbed if growth is poor mulch in the spring with animal manure *Prop*—Generally done by seed in spring special forms by grafting

Hamamelis—A lovely but little grown winter flowering heavily scented shrub The delicate lemon coloured flowers appear interminably from December to February Although it flowers in its young stage hamamelis is slow to get established and must be left free of root disturbance The best sort is *H. mollis* introduced from China in 1879 *Prop*—Usually by grafting can be layered.

Heather—See *Erica*.

Hedera—Although ivy is seldom planted nowa days there are a few evergreens to equal it for covering buildings. The large leaved ivy with golden variegation *H. colchica* Dentato Variegata is invaluable for cold or shady walls. *Prop*—Cuttings in August in shady border out-of-doors.

Helianthus—The perennial sunflowers are tall yellow flowered plants of vigorous habit. They spread quickly and become a nuisance and therefore clumps should be lifted and single rooted pieces replanted every other year. The annual sunflower may reach a height of 10 ft or so seed is sown out of doors in April or seedlings raised under glass in the spring. When the flower bud appears feed with soft water. The seed may be used as food for large birds like parrots.

Helichrysum—Although this is a large group of plants the most interesting is the half hardy annual *H. bracteatum* the everlasting flower. When the flowers are fully developed they are cut with long stems and hung up to dry for winter-decoration. *See Annual*.

Heliotropium peruvianum (Cherry Pie)—Scented shrubby plants used for greenhouse decoration or summer bedding. *H. Sir Edward Fry* is among the scented varieties and *H. Francesc Marini* is the best dark purple variety. They really good results heliotropes need a rich soil and plenty of water in summer. *Prop*—Cuttings 2-3 in. long in early autumn or spring struck in sandy loam in a warm greenhouse.

Helleborus—The Christmas rose *H. niger* should be planted out of the direct sun in a moist soil which has been liberally enriched with leaf mould and old manure and here left free from root disturbance. Its large white flowers appear irregularly from December to February with early flowering encouraged by protection with cloches. The Lenten rose *H. orientalis* flowers from February to April and it is well worth searching nurserymen's lists for varieties with a wide range of colours. *Prop*—Division of clumps in the spring with each piece having four or five growth buds. The clumps should not be split into small pieces.

Hemerocallis—Hardy perennial for moist border either open or slightly shaded. Mulch established clumps in the spring with compost or manure. Many new varieties are coming on the market as a result of introductions from America where the plant is popular. *Prop*—Division.

Hibiscus—The evergreen, shrubby sorts with large exotic flowers are widely grown in the tropics and can be seen under glass in botanic gardens in Britain. *H. syriacus* is a deciduous hardy species little pruning is required and in full sun it will reach 8-10 ft. Normally it is a free-flowering plant of great beauty and, in cases where the flowers fail to develop the stock is best replaced with good varieties, like *Coeleste* (single blue) and *Woodbridge* (single red). *Prop*—Cuttings under glass grafting.

Holly—See *Ilex*.

Hollyhock—See *Althaea*.

Honeysuckle—See *Lonicera*.

House Leek—See *Sempervivum*.

Hyacinth—Bulbs generally used for bowl culture often results are disappointing but responsibility does not necessarily rest with the nurseryman, as poor cultivation is the most probable cause. Plant in September-early October (not later) in peat loam and sand, and keep as cool as possible until growth starts when bowls may be brought into a warm room. Care must be taken with watering as the bulbs must not dry out nor the compost allowed to become wet and soggy. After flowering plant out-of-doors and lift annually in June for replanting in the autumn for bowls a fresh stock is required every year.

Failures are mostly due to late planting or faulty watering.

Hydrangea—A favourite shrub introduced from the Far East. Of the many forms the one offered by florists *H. macrophylla* is the most popular. This can be bought in a wide range of shades from white and pink through to crimson and blue. The colour will depend on soil reaction. In alkaline or neutral soils only white and pink shades can be grown and blue flowers will be found only on acid soil. The intensity of colour can be improved by adding lime in the first instance and flowers of sulphur in the second but it is not possible to make an alkaline garden soil acid in reaction. Lack of flower is generally the result of buds being killed by cold weather. For this reason hydrangeas are best not pruned until the late spring then old flower heads and any weak or unwanted growth can be cut out. During summer the plants must not suffer from lack of water.

Among the many other sorts are *H. paniculata* with large cone shaped panicles of flower and *H. petiolaris*. The latter plant is a vigorous climber well suited to cover cold walls or for climbing over dead trees. *Prop*—Cuttings in July-August in a cold frame.

Iberis (Candytuft)—The hardy annual sorts will thrive in any soil and may be had in a range of colours. *See Annuals*. The perennial candytuft (*I. sempervirens*) is a good plant for a rock wall and has white flowers in early spring. *Prop*—Seeds in spring, and cuttings in summer.

Ilex—The ornamental value of our native holly is rarely fully appreciated bearing in mind that on good varieties the berries sometimes persist until March. The greenish flowers are sometimes bisexual and sometimes male and female flowers are on separate plants. For this reason hollies should be planted in groups and at least one plant of good berrying habit like *I. aquifolium* Pyramidalis, grown. Some varieties have yellow berries and gold or silver variegations on their leaves. *Prop*—Seed special forms by budding.

Iris—This plant is divided into two main sections those types which grow from bulbs and those which grow from fleshy rhizomes with many subdivisions in each of them. Of the latter type there are the commonly grown bearded flag irises which owing to their ease of cultivation and wide range of colours, are appropriately known as the poor man's orchid. Notwithstanding these irises respond to good treatment doing best in well drained soil to which a little manure has been added and a dressing of rough chalk forked into the surface. The site should be in full sun for preference and one that never lies wet in winter. Planting or division of established clumps is done in July setting the rhizome on the surface of the soil but firming the roots well. To maintain growth and flower feed annually in the spring with equal parts of superphosphate and bone meal at 3-4 oz. per sq. yd. Iris gardens are not often found nowadays but the fine example still maintained at Kew is well worth close inspection.

In the bulbous section the Siberian iris is a graceful plant with delicate foliage though much smaller flowered than the flags. They make a fine waterside planting or may be grown in the herbaceous border. The Japanese iris is another water lover and this has delicate-coloured clematis like flowers. On the other hand, for dry poor stony soils in full sun the lovely winter flowering Algerian iris *I. unguicularis* (stylosa) is an ideal plant flowering as it does in December and January. This is a plant which must be kept undisturbed after planting in June and if leafy growth is excessive the foliage can be cut back by half in August. Spanish, Dutch and English types of bulbous iris are often used as cut flowers. These may be planted in ordinary garden soil in the autumn and left undisturbed until signs of deterioration are found.

Japonica—Common misnomer of *Ohaenomeles* (q.v.).

Jasminum—The yellow flowered, sweetly scented winter jasmine blooms intermittently

from November to February. It grows in any soil and is best trained up a wall or grown on a trellis. Pruning consists of cutting out the flowering shoots as soon as the blossoms fade. The summer jasmine is a vigorous climbing plant with white scented flowers. It needs a sunny position and should be well thinned after flowering. *Prop*—Layering in summer.

Kalmia.—Hardy American shrub, with clusters of waxy rose or pink blossoms in early summer. Although slow to get established and requiring a damp acid soil, the plant is well worth growing. It constitutes a feature of the garden of the National Trust at Sheffield Park, Sussex. *Prop*—Seed or layering.

Kerria japonica—A hardy shrub which will thrive in any garden but is best fed with manure to encourage strong growth. When the yellow flowers fade the stock should be kept vigorous by cutting out old or weak growth. The plant is named after William Kerr, a young man despatched from Kew to collect plants in China. *Prop*—Division in autumn.

Kniphofia (Red-hot Poker)—Although these plants are so commonly seen their full value as late flowering subjects is not often fully explored. There are a number of good varieties worth growing such as *Maid of Orleans* (white 4 ft.), *Mount Etna* (scarlet 5 ft.) and *Royal Standard* (gold and scarlet 4 ft.). Of equal value is the dwarf variety with grass like foliage, *K. nelsonii*. *Prop*—Division in March, easily raised from seed if so desired.

Laburnum.—Handsome trees with long racemes of yellow flowers the seeds of which are very poisonous. It is not advisable to remove branches as wounds do not heal off quickly and once a specimen shows signs of deterioration it is best replaced with little delay. *Prop*—Seed or grafting.

Larkspur—See *Delphinium*.

Lathyrus (Sweet Pea)—For general garden decoration seed may be sown in pots in a warm greenhouse in early February prior to transplanting out of doors in April. When heat is not available sowing can be done in the open in October setting the seed 4-6 in. apart and 2 in. deep where the plants are to grow. In this case the rows are best protected by cloches. As the plants flower with great freedom and make strong growth, a rich deep soil is required. During the summer water should be given freely and liquid animal manure or soot water applied weekly when flowering starts. When raised for exhibition special cultural treatment is necessary. The cause of the condition referred to as bud drop is not known but it is thought to be connected with low temperature and faulty root action.

There is also the hardy perennial sweet pea, an old world plant usually seen at its best in cottage gardens. This plant requires the same cultural conditions except that the old stems are cut down in the autumn. Three or four different species are available and all are easily raised from seed sown in the spring.

Lavandula.—The lavender is one of the best known of garden plants. It thrives in full sun in a light soil, old flower heads should be clipped off in the summer, but any cutting back into old growth must be left until the spring. The best garden form is *L. spica* *Nana Atropurpurea*, it has a neat dwarf habit, with deep purple flowers, and is available from leading nurserymen. *Prop*—Cuttings out of doors in August–September.

Leucojum.—The spring snowflake flowers in February and is a charming plant for any damp shady border. Although it has a large flower it has never become as popular as the snowdrop despite its ease of culture. It should be grown by everyone who values early spring flowers. *Prop*—Lift clumps and replant after removing offsets in August.

Lilac.—See *Syringa*.

Lilium.—The lilies constitute a large genus of plants some of easy culture, some demanding the most exacting of conditions. For a soil containing chalk two of the best lilies are *L. candidum* the Madonna lily and *L. regale*. The former is a feature of many gardens in South Wales where bulbs are planted near the surface of the soil and the clumps eventually left to develop undisturbed. Only the easiest grown lily is suitable for the herbaceous border and here apart from the Madonna lily the tiger and martagon lilies should be first choices for beginners in the cultivation of this genus. *Prop*—Those referred to above may all be raised from seed sown out of doors (or in deep boxes in a cold frame) in the spring. In the following April line out into nursery rows prior to transplanting to flowering positions. Also propagated by offsets and bulbils.

Lily of the Valley—See *Convallaria*.

Loebelia.—The bedding lobelias are perennial plants best raised as annuals (qv). They do well in a light soil but should be firm at planting time to prevent plants dying off during a hot spell. The handsome tall growing lobelias with scarlet flowers like *L. fulgens* *Huntsman* may be used in herbaceous borders with great effect but the roots must be lifted and overwintered in a cold frame. These sorts grow to a height of 2-3 ft. and will do well only on a wet heavily manured soil.

Lonicera.—The honeysuckles make effective climbing plants if grown on the shady side of arches or tree stumps or against north or west walls. Care should be taken to train young growth before it becomes hard. Old shoots may be cut out each spring to keep the plant within bounds although space must be available for free development. If growth and flowering is poor mulch the roots in the spring with old manure. *Prop*—Easily done by layering in late summer.

Lupinus.—There are two sorts of lupine, perennial and annual. The herbaceous perennials are among the most colourful of plants as a result of the famous Russell strain being introduced. Of late years, however, the constitution of the plant has been weakened through perhaps breeding and virus diseases and it should be taken for granted that most stocks have to be replaced every two years or even annually in some cases. The plant requires a rich soil and is best in ground free of lime. Conversely in poor soil the tree lupin thrives and will reach a height of 7-9 ft. plant in full sun and heavily manured into shape after flowering. *Prop*—Both sorts are best raised from seed sown in May out of doors and transferred to flowering positions in October. The annual lupin may be obtained in a range of colours and should be grown in full sun. See *Annals*.

Magnolia.—Richly said to be one of the most beautiful of all flowering plants. Contrary to popular belief some kinds are of easy culture flowering when young and suitable for small gardens. Of course careful selection is necessary and for a specimen on a lawn *M. Soulangiana* (large white or white purple stained flowers) is ideal. *M. stellata* really flowers in the young stage and may be planted in an ordinary border if the soil is lime free. To encourage growth mulch annually with peat or leaf mould, but never dig near the roots. The evergreen magnolia is often seen as a fine wall plant in old gardens. This is the only species which may be pruned and long shoots can be cut back hard in April. There are a number of non flowering strains of the evergreen one, and unsatisfactory plants are best destroyed as flowering cannot be induced in buying a replacement care is necessary in order to avoid another dud. *Prop*—Seed sown as soon as it is ripe in October, layering.

Mahonia.—Hardy evergreen shrub of great merit if grown well. *M. aquifolium* is useful as ground cover thriving in any soil and in shade if protected from cold winds. *M. japonica* has long racemes of lemon scented flowers in winter inferior sorts are often listed by nurserymen under this name. Of equal merit is *M. Charity*.

which by reason of its flowering in November warrants a place in any garden if free from exposure to wind. Foliage sought after by flower arrangement groups. *Prop*—Seed, suckers layers, cuttings in August.

Matatola.—The night-scented stock is a hardy annual with insignificant purplish flowers which open at dusk, grown primarily for its perfume. Conversely the so-called Ten Week stocks and a selection of these the East Lothian stocks have a wide range of colours. If sown in March they may be used for summer bedding or if sown in August overwintered in a sunny frame and grown as a biennial.

Brompton stocks flower earlier than the other sorts and are grown as a biennial by sowing seed in June or early July and after pricking out into boxes are overwintered in a sunny frame. In

as by careful selection of varieties a long season of flower can be obtained when they are grown in formal borders or naturalised. Thus a season may be extended with Peeping Tom and Covent Garden (early) and Geranium and Buttercup (late). The bulbs can be left undisturbed until flowering is affected by over-crowding the clumps should then be lifted and divided in the late summer. To maintain vigour feed annually in February with 2 part bone meal 1 part hoof and horn meal and 1 part sulphate of potash at 2-3 oz per sq yd. The chief troubles with narcissi are due to eelworm (T29) and the narcissus bulb fly (T-3). For indoor work plant in bowls in October and keep in cold place until growth is an inch high. Failure is invariably due to premature forcing or faulty watering.

Nasturtium—See *Tropaeolum*.

WATER LILIES IN TUBS.—Drawing (A) shows a cross section with correct percentage of water and soil together with water lilies and fish. Drawing (B) illustrates marginal planting with primulas, Japanese irises and a dwarf coniferous tree.

mild districts if the soil is well drained stocks may be planted out-of doors in the autumn, but a reserve should be kept for filling up gaps in the spring.

Meconopsis.—This genus includes the famous blue poppy introduced from the Himalayas. It is not a plant of easy culture, albeit large groups are grown in many woodland gardens where soil conditions permit. After flowering the plants generally die although an occasional plant may persist. *Prop*—Seed sown in March.

Michaelmas Daisy—See *Aster*.

Montbretia.—This bulbous plant is of easy culture and has a long season of flowering. Many new varieties with large flowers are now available and growth can be kept vigorous by lifting and dividing the clumps every three or four years. Plant in early spring 4 in deep and 6 in. apart and in cold gardens protect clumps in winter with a covering of ashes.

Myosotis.—The forget-me-not is grown as a biennial by sowing seed in May and planting out in the autumn in conjunction with spring flowering bulbs and wallflowers. Poor varieties freely establish themselves and these should be destroyed before planting any of the really good sorts offered by seedsmen.

Narcissus.—This botanical name includes plants commonly known as daffodil and narcissus. Although often grown the wide garden value of these spring flowering bulbs is not fully realised

Nepeta (Catmint).—In recent years this edging plant with silvery foliage and mauve flowers has become increasingly popular. When flowering in mid-summer there is no finer display of colour. It grows freely on any light well-drained soil in full sun. The best sort is *N. faassenii*. *Prop*—Division of clumps in March.

Nerine.—Lately this lovely bulbous plant has increased in popularity mainly through the varieties introduced from the late Lionel de Rothschild's garden at Exbury. The hardy sort *N. bowdenii* flowers in the autumn and should be planted at the foot of a warm wall in August or September and left undisturbed for many years. As the bulbs gradually multiply and work to the surface a light dressing of sandy compost to which has been added a little bone meal can be applied. *Prop*—Separation of bulbs in August.

Nicotiana (Tobacco Plant).—This half-hardy annual is grown mainly for its heavily scented flowers which open in the evening. It is worth remembering that the white-flowered sorts are the best in this respect, scarlets and pinks are very much inferior. See *Annals*. The tobacco of commerce is a different plant, namely *N. tabacum*.

Nymphaea.—No branch of gardening is more fascinating than the water garden, and for it the chief plant must be the water lily. Basically the main reason for failure is in the fact that in most pools the average depth of water is less than 18 in. This means that the water is liable to be adversely

affected by extremes of temperature. All nym phaeas should be grown in full sun and where the water is still in streams it is necessary to utilise a little backwater out of the current. Water lilies are planted in May in large wicker baskets with a compost of three quarters of loam and a quarter of peat, alternatively planting sites can be built up with bricks to the desired height. If growth is poor mould Clay's Fertiliser into the size of pigeons eggs and drop one around each clump. To maintain a healthy condition in the water fish should be introduced as soon as the plants are established. *Prop*—Division of tuberous roots in late May.

Orchids—In the main this large group of plants needs greenhouse conditions and specialised knowledge. Their cultivation has attracted the attention of some of the greatest of horticulturists and detailed references may be found in books like *Orchids their Description and Cultivation* by C. H. Curtis (Putnam) 1950.

Paeonia—There are two sorts of paeony the tree paeony and the herbaceous paeony. The former needs a sheltered warm position and takes about three years to flower from planting time. The latter sort needs a moist rich soil and should be mulched annually in the spring with well rotted manure, some are known not to flower and as such plants cannot be induced to do so they should be destroyed. The old fashioned variety of paeony has been superseded by many fine new varieties found listed by specialists. *Prop*—Tree paeonies by layering or seed sown in the autumn, herbaceous sorts by seed or division.

Pansy—See *Viola*.

Papaver (Poppy)—The oriental poppy is a hardy herbaceous perennial with striking flowers intolerant of shade and root disturbance. As it blooms early it should be set near the back of a border as the large leaves look untidy later in the year. Apart from the commonly grown red flowered sort there are others in shades of crimson, pink and lavender. *Prop*—A wide range of colours can be obtained by sowing mixed seeds in May. This is a better method than division. The Shirley poppy is a hardy annual (q v) while *P. nudicaule* is a biennial needing a warm sheltered position.

Parthenocissus (Virginia Creeper)—This climber with its brilliantly coloured leaves makes a fine sight in the autumn and there is no better plant for covering brickwork or unsightly buildings with a south or west aspect. It has been suggested (mainly by builders) that the plant will damage stonework or cause dampness. There is little evidence to support these suppositions and reasons for damage can usually be traced—often without difficulty—to other sources. The plant has had a number of names—*Ampelopsis vesicularis* is one—but up to date nurserymen are listing it correctly as *P. tricuspidata*. *Prop*—Cuttings out of doors in the late summer layering.

Passiflora caerulea (Passion Flower)—A south wall in favoured gardens is needed to grow this plant. It is of vigorous habit and once the framework of branches has been produced it should be pruned annually in the early spring by cutting back all the previous season's growth to 2-3 in of the main stem. *Prop*—Layering.

Pelargonium (Geranium)—So-called bedding geraniums such as *P. carolinianum* are really zonal pelargoniums. To maintain a stock, take cuttings in early August and insert in sandy soil around the edge of a pot and overwinter in a frost free greenhouse. In the spring pot up singly and use for bedding. Otherwise pot on after two months and if early buds are nipped off plants can be adopted for late flowering indoors. Pelargoniums are easy to grow but for best results a position in full sun is necessary and cuttings should be rooted before the autumn so that overwintering constitutes no great difficulty.

Petunia—Although really perennials, these plants, native of South America, are treated as annuals (q v). They are sun lovers and do best

on light soils. Petunias make fine plants for sunny window boxes and particularly happy combinations can be made by planting together varieties such as *Viola* (deep violet) and *Cheerful* (pale pink) or *Flaming Velvet* (crimson) and *Cream Star* (pale cream). The violet flowered sorts are faintly scented.

Philadelphus (Mock Orange)—Although some fine varieties of this shrub are available in the trade it is not grown as widely as its merit deserves. As a scented shrub it has few equals while it is tolerant of poor soil conditions and shade. Particularly good sorts worth searching for are *Albatre* (double), *Beauclerk* (single) and *Sybille* which at 3 ft is about half the height of the others. After flowering prune annually by removing as much old flowering wood as possible. *Prop*—Hard wood cuttings out of doors in November.

Phlox—A wide range of varieties of the border phlox are offered to make an impressive display late in the season. If grown on light soils some shade is desirable as phloxes do well where only the soil is damp. For this reason mulching should be done annually in the spring with compost or animal manure. Failures are usually due to eelworm (T30). *Prop*—Seeds in autumn division.

Poppy—See *Papaver*.

Polyanthus—See *Primula*.

Polygonum—In the main these plants are weeds of gardens although originally they were introduced from the Orient for ornamental purposes at a time when their invasive habits were not fully appreciated. The one woody climber in the genus *P. baldschianum* makes an admirable cover where a very vigorous plant is wanted. Rampant and unwanted species may be eradicated by hormone treatment (T34).

Primula—Polyanthuses primroses, greenhouse primulas and the hardy primulas all belong in this genus. The first two are the most popular, both will do well only in damp soil and respond to generous manurial treatment, both are available in a wide range of colours. *Prop*—The Black more and Langdon strains of seed will give a magnificent display of mixed colours. Sow in warm greenhouse in early March or cold frame in April, prick out into boxes and transfer to flowering positions in the autumn.

Prunus—A large genus which includes the flowering peaches, Japanese cherries and flowering almonds. All of them are best left to develop

REMOVAL OF SUCKERS—As illustrated these must be sawn off into the root or pulled off the root with a sharp tug and never so removed that dormant buds are left.

naturally and are not responsive to pruning or cutting back in any way. A few sorts are overplanted in gardens and as street trees (by Park Superintendents) but anybody wishing to be a little out of the ordinary would do well to see the wide range of some of these lovely trees flowering in April and May in our botanic gardens and many of the large gardens now under the jurisdiction of the National Trust. The selection offered by nurserymen is often strictly along conventional lines. Lack of flower in some seasons can often be traced to bird damage.

Red-hot Poker—See *Kniphofia*.

Rhododendron—Greenhouse and hardy ever green and deciduous shrubs including *A. alba*. With something like ten thou. and different sorts it is impossible to deal with individual requirements. General cultivation: an acidic soil is essential with adequate moisture in summer. If growth is poor on established plants mulch liberally with animal manure. Beginners should plant from the accepted list of hardy garden hybrids. Since the turn of the century widely planted and fine examples are to be found for instance in many gardens of the National Trust. *Prop*—Seed and layering.

Romneya.—Since its introduction from California in about 1850 the plant has proved a fascination to gardeners as sometimes it fails completely

will control mildew provided the bushes are well mulched and watered. Captan or maneb should be used immediately after pruning and throughout the summer to control black spot, but thiram for rust control need not be used until the disease appears. Good manurial treatment including foliar feeding will help to prevent disease. For control of greenfly see *Aphids* T29.

For a manurial programme an application of 2 parts of superphosphate and 1 part of sulphate of potash should be applied at 3 oz per sq yd after pruning. Following this a surface mulch of animal manure, compost, peat or leaf mould or a mixture of all of them is given about 2-3 in thick. Subsequently if growth is poor a dressing of nitro-chalk can be made at 1 oz per sq yd.

Where soil conditions are poor and disea-

PRUNING ROSES—(A) A vigorous unpruned plant (B) The same plant pruned for the production of exhibition blooms (C) and pruned for garden decoration.

or does exceedingly well. It appears to require a light soil and a sheltered position, preferably against a sunny wall and there is no point in trying to grow a romneya on a heavy wet soil. Usually the annual stems die off in the winter and may be cut down at ground level in the early spring. If persistent the stems can be cut back to sound growth. The new growth is susceptible to slug damage and appropriate steps must be taken (T29). *Prop*—Seed or suckers taken off in the spring.

Rosa (Rose)—Undoubtedly the rose is the most popular of all garden flowers, and it may be found in a multitude of forms. The dwarf roses for bedding may be grown on most soils but are best on a rich heavy loam. Planting is done from early November onwards when soil conditions permit and the first pruning carried out in the following spring when the extent of any winter damage can be seen. Opinions differ sharply on pruning: a sound general rule is to do the work in March and—unless there are special circumstances—to prune on the light side. Thus for Hybrid Teas and the like reduce strong stems by about one third of their length, medium ones by a half and weak ones to within two or three buds of the main stem.

Whatever sorts of soil roses are grown in, feeding is important but of course it is particularly so on poor ones. It is in soils of low fertility that diseases such as rust and black spot are most prevalent and in some measure, persistence of the disease is due to bad cultivation and lack of treatment with fertilisers. Regular dinocap sprays

arevalent. It is important to buy plants only from nurserymen who take special precautions to ensure that their customers have disease-free stock. Likewise varieties of robust constitution are essential and a selection list may include *Hybrid Teas*, Ballet (pink), Eden Rose (magenta pink), King's Ransome (yellow), Perfecta (pink and white), Super Star (coral orange) and Wendy Cussons (rosy red), *Floribundas*, Circus (bicolour yellow/scarlet), Dusky Maiden (crimson), Iceberg (white), Queen Elizabeth (pink) and Spartan (deep salmon).

In most of the modern hybrids scent is almost absent. The true rose perfume is found only in the Old Fashion or shrub roses and, normally these are planted in a mixed shrub border. For the richest perfume varieties like Mrs. John Laing and Conrad F Meyer should be sought.

Salvia.—Annuals, perennials and tender shrubs. The most popular one is the scarlet sort used for bedding. It requires careful attention, and seed should be sown in February in a temperature of 60° Fahrenheit and seedlings put into single pots when large enough. Gradually the young plants are hardened off and finally planted out in rich soil in a sunny bed.

Saxifraga.—A large genus of plants suitable for the rock garden and valued for their bright flowers in the spring. The encrusted saxifrages are cushion-forming plants requiring sharp surface drainage and an open position out of the direct

sun. The mossy saxifrage are mat forming in growth and of easy culture. In time old clumps develop brown patches and then require splitting up and replanting in the spring.

Scabiosa.—The commonly grown perennial sort is *S. caucasica* and is invaluable as a cut flower. It is not at home on all soils and only does really well in a deep rich loam containing plenty of chalk. In addition it must be grown in full sun and particular care taken against slugs. **Prop.**—Old plants divided in the spring and rooted pieces replanted in their flowering positions. A wide range of shades in white, blue and purple can be had normally from sowing mixed seed in April.

Sedum.—The stonecrops make up a large group of hardy and tender plants but comparatively few are of horticultural value. Notwithstanding *Sedum spectabile* is to be found in most herbaceous borders where its fine flat heads of pink flowers are a feature for many weeks. It is beloved by bees and butterflies. *S. sedoides* was introduced from Japan about 100 years ago and, although hardy, it is usually grown as a house plant. In the winter it can be stood out of doors and every two or three years repotted in the spring, keep well watered during the summer and feed with liquid manure occasionally. **Prop.**—Division in the spring.

Sempervivum (House leek).—These hardy plants with succulent leaves often decorate the crevices of old walls and are regular features of trough or sink gardens. If given a light, poor soil and a position in full sun a fascinating collection of house leeks can be built up. The species which gives the plant its common name can be established easily on a sunny roof by planting in a mixture of cow manure and clay during the spring. **Prop.**—Division in the spring.

Skimmia.—A hardy evergreen 2-3 ft. tall which is tolerant of shade and some degree of dryness. If growth is poor water with a liquid manure and mulch with peat or leaf mould. Some forms bear only male flowers and to ensure a good crop of berries plant an hermaphrodite like *S. foremansii*. **Prop.**—Layering in the autumn.

Snowdrop.—See *Galanthus*

Snowflake.—See *Leucojum*

Solanum elaeagnifolium (Winter Cherry).—A berrying plant with bright red fruits which is often used for house decoration. To maintain the plant in a healthy condition it should be clear of draughts and fumes of gas fires and the foliage kept fresh and free of dust by vigorous syringing. If the stock is to be kept for more than one season water should be given only sparingly in the New Year and in early March all the side shoots pruned back hard to within a bud or two of the main stems. As new growth develops water can be given more freely and syringing started when the flowers first appear. Liquid manure will prove beneficial when berries develop.

Spiraea.—Hardy deciduous shrubs for open borders tolerant of poor soil conditions. The commonly grown one is *Spiraea bumalda* (syn. *saponea*). After flowering a percentage of the old wood should be removed together with any weak growth, and development of new shoots encouraged by mulching with compost or animal manure. **Prop.**—Cuttings rooted in sandy soil under a hard light in summer suckers thinned out in winter.

Stocks.—See *Matthiola*

Sunflower.—See *Helianthus*

Sweet William.—See *Dianthus*

Symphoricarpos (Snowberry).—Often found existing in deep shade and in competition with roots of overhanging trees, presumably as a result of the generalisation that the shrub is a shade lover. Certainly a useful one in this respect but it is responsive to good treatment. Given an average soil and if growth is thinned annually in

the early spring then *S. albus* *laevigatus* is well worth having. Its large white fruits are untouched by birds and hang well into the winter and are thus beloved by the floral decorator. **Prop.**—Suckers removed in the winter.

Syringa (Lilac).—The botanical name of *Syringa* is often erroneously applied to the Mock Orange correctly named *Philadelphus* (qv). A wide selection of first class varieties are available in nurserymen's lists. To obtain heavy crops of flowers nip off all dead flower heads as the blossoms fade but do not cut back into the old stem as this will prevent flowering. At the same time any branches causing overcrowding can be removed. Annually feed with National Grow more at 2 oz per sq. yd. and on sandy soils mulch with any sort of manure or compost. **Prop.**—Layering in the autumn.

Tagetes (Afr. can. and French Marigolds).—Half hardy annuals of free flowering habit and easiest culture. Best if fed generously with soot water or other nitrogenous manure during growing season. See *Annuals*.

Tropaeolum.—The common nasturtium and the flame flower (*T. speciosum*) belong to this genus. The former is easily grown from seed sown in May in a sunny position. The latter is a very difficult plant to grow outside the conditions which it demands. To be successful this perennial climber must be planted in acid soil which is naturally damp and lightly shaded but yet where the new growth can reach full sun. Much disappointment often results from planting it in eastern England for instance after seeing it flourishing almost as a weed where the rainfall is high in Ireland and the west of Scotland.

In the genus will also be found the canary creeper which can be used for screening purposes and will thrive in full sun or shade. Seed is sown in May in open ground and light supports supplied by way of pea sticks or strings. Failure is normally due to nothing more than lack of moisture.

Tulipa (Tulip).—Thrives in a deep rich loam but will do well for one season in ordinary garden soil. When used for bedding bulbs must be lifted after flowering replanted in a trench and thoroughly watered. Sometimes tulips may be left in the ground if conditions are favourable and then the stock only needs lifting and replanting every three years. To check the incidence of tulip fire plant in late November or early December covering the bulbs with 4 in. of soil and treat the ground with a fungicide like Botrylex. Before doing so rake in a dressing of 2 oz super phosphate and 1 oz sulphate of potash per square yard. A national collection of wild tulips is being got together at Cambridge and grown there in the University Botanic Garden.

Viola.—This name embraces pansies, violas and violets. Although the viola has not got the rich colours of the pansy (or its attractive markings) it has got a remarkably long season of flower and for this reason it is invaluable as an edging plant or as ground cover for roses. **Prop.**—Both plants are easily raised from seed sown in a frame in the spring pricked out and then transferred to their flowering positions in late May. Alternatively seed may be sown in July for planting out in October. Named varieties increased by cuttings in a frame in late summer.

Virginia creeper.—See *Parthenocissus*

Wallflower.—See *Cheiranthus*.

Water Lily.—See *Nymphaea*.

Winter Sweet.—See *Chimonanthus*.

Wistaria.—One of the finest of all climbing plants for south or west walls or stout pergolas. Plants which do not flower or only do so poorly are probably seedlings and the true flowering habit cannot be induced. The only solution is to replace with a grafted plant of known flowering capacity from a reliable nurseryman. All young shoots not required for the extension of branches should be shortened to within 3 in. of the old stem in the

autumn. Winter's growing over trees do not require pruning. *Prop*—Layer shoots of current season's growth in the autumn.

Zinnia.—Half hardy annual ideally grown on moist deep loam liberally enriched with well decayed manure. Mulch with manure after planting and apply liquid fertilizer as buds appear. Plants must not suffer from lack of water. *S* Annual.

MAKING A LAWN

In almost every garden the most prominent feature is the lawn and often a lot of work is put into making one without any great measure of success. Usually the reason for failure may be found in faulty preparation of the soil or premature sowing, albeit the blame is often placed on bird damage or poor seed.

For anything like a reasonable turf the site must be thoroughly dug and the content of organic matter increased by incorporating generous quantities of materials like peat, leaf mould, compost, sewage sludge and animal manure. A dressing of these ingredients can be applied in a layer 3-4 in. thick and buried in the bottom of the top spit of soil. As the ground is dug to incorporate the organic matter root of perennial weeds should be removed.

If the site is one on which water tends to lie or if the soil is heavy then surface drainage should be sharpened by forking into the top 2 or 3 in. a liberal application of some coarse material such as builders' rubble, road grit, screened ashes or coarse sand. In some cases this treatment will not be sufficient and then the installation of land drains must be resorted to. This particular task is not as difficult as is sometimes imagined, but before a start is made it is always a good plan to discuss the matter with an experienced man.

After the initial work a fine tilth on the soil may be obtained by thoroughly raking and cross-raking and at the same time establishing a level surface. On this point it should be remembered that good lawns can be made on undulating ground or on natural slopes, but the things to avoid are the shallow depressions where water will naturally tend to lie. Finally ten to fourteen days before sowing the subsequent growth of grass can be encouraged by making an application of National Growmore at 2 oz per sq yd.

Sowing is best done in the late summer at a time when the soil is moist. For the purpose a good mixture of seed should be obtained from a reliable seedsmen and it is worth paying a reasonable price for it as, by and large the coarsest and roughest grasses have the largest and heaviest seeds. Opinions differ on rates of sowing but with care and in a well prepared soil 1 oz per sq yd. is ample. Heavier rates will give quicker results, but the density of seedlings in such cases often leads to the finer grasses being choked by the coarser ones.

After sowing the ground should be lightly raked but not rolled. At this stage the important point is to protect the seed bed from birds by the use of hazel sticks, strings of papers tied to stakes after they have been dipped in lime-wash, and strands of black cotton. Subsequently annual weeds may appear in quantity, these are of no consequence and they will be eliminated once the grass is cut regularly. Until a good turf is formed—usually about twelve months after sowing—it is not desirable (or probably necessary) to use hormone weed killers. See T35

Care of Established Lawns.

Most turf is never manured from year to year and the soil may seriously lack plant foods. In the first place this can be corrected by making an application annually in the spring of National Growmore at 1 oz per sq yd. Following this if growth is below par in the early part of the year an application of sulphate of ammonia can be made at the same rate. To avoid scorching or blackening of the foliage each fertiliser can be mixed with equal parts of dry soil or sand as a carrier to ensure even distribution and what is most important each one should be applied only when the turf is wet and there is the prospect of rain to follow. Linked with this treatment turf is always responsive to top dressings. A compost for the purpose can be made up with

2 parts of loam
1 part of sieved compost
1 part of fine peat or leaf-mould.

This may be used in the spring at 3-5 lb per sq yd and if the soil is heavy 1-2 parts of gritty sand may be added.

With the introduction of new designs in motor mowers most lawns are seriously overcut and this has led to a sharp decline in the quality of the grass and the appearance of one or two pernicious weeds. It is appreciated that special turf such as that found on a bowling green may be shaved off to ½ in. but if a utility lawn is cut below half to 1 in. then the quality of the grass will deteriorate. Of course it is a good thing to occasionally cut the grass very short, but conversely if the blades of the mower are set as low as possible and left like it throughout the season nothing but harm can result. The reason for this hard fact is that when the turf is cut very close the grasses simply cannot develop and spread, and weeds will gradually establish themselves. Eventually the cultivator will be faced with the difficult problem of trying to deal with such plants as pearlwort, yarrow and various mosses, all of which are resistant to hormones.

As for the vexed question of whether or not to remove the mowings there is no doubt that the best turf is found where the mowings are collected up although in very dry weather they can be left on the surface. If the clippings are not removed the surface of the turf tends to become choked with semi-decayed organic matter and conditions are brought about which are conducive to the spread of moss.

Finally it is worth noting that the finest turf is found on acidic not alkaline soils. For this reason lime should not be applied as a general rule for apart from helping the development of coarse grasses, it encourages the growth of clover. Of course there are times when lime is necessary but the occasions are rare and before it is used it is a good plan to test the soil by chemical means.

THE FRUIT GARDEN

The guidance of an expert is probably more important in the growing of fruit than for most of the commoner vegetables and ornamentals. This is primarily because the majority of fruit trees and bushes are long lived, and only in the case of strawberries can a change of site or variety be made easily and inexpensively.

Gardens which are low lying are very prone to damage from spring frosts, and should not have too much space devoted to fruit as returns may well prove unprofitable. Here, as with the selection of varieties, advice of a local expert is invaluable. Some varieties do better in certain localities and on certain soils than others, although personal preferences will naturally be met where possible. Varieties chosen should cover as long a season as is practicable so that the fruit can be used and enjoyed to the full.

Tree fruits are grown on a rootstock, and for apples and pears special dwarfing stocks make these a possibility for the small garden. It is therefore important to explain to the nurseryman what type of tree is required. As a general rule however the smaller gardens will gain by concentrating on currants, gooseberries, raspberries and strawberries. Plums and cherries have no

dwarfing stocks and should be included only where sufficient room is available

Apples—Can be grown on most soils. Manure should not be used when planting, except in sandy and chalky gardens. Obtain trees on dwarfing rootstocks such as M.IX, M.VII or MM 106. Always stake trees on M.IX otherwise this practice is necessary only in exposed sites. The tie must be rigid with a cushion between tree and stake to avoid chafing and must be renewed annually to avoid constriction. Plant between late October and early March preferably before Christmas if soil and weather allow. Make the hole large enough to spread the roots evenly, firm thoroughly while filling in and plant level with the nursery soil m.k. already on the tree. Mulch around each tree with manure or compost mainly to avoid drying out and supplement with watering during the summer when necessary.

In the first year any flowers produced are best pinched out to encourage root and shoot development. For walls or fences use oblique cordons or espaliers, these are also useful for flanking paths and lawns. Plant cordons 2½ ft. apart with 6 ft. between rows and espaliers 12–15 ft. apart. For larger areas use bush trees 12–15 ft. apart.

Manuring for cropping trees should be varied according to growth. Generally apply 1 oz. sulphate of ammonia (or nitro chalk on acid soils) in early March repeating this in early April if trees are growing in grass. Give ½ oz. sulphate of potash in February and add 3 oz. of superphosphate every third year. The above rates are per square yard and a complete fertiliser can be used in lieu if preferred.

Young bush trees should have main shoots reduced by half in early years to produce strong branches. Thereafter prune side shoots to three to six buds. For weak growers prune harder and for strong growers prune less. It is wiser to leave a strong tree unpruned than to prune it too severely, the latter merely encouraging even stronger growth. A few varieties (e.g. Bramley's Seedling, Worcester Pearmain) fruit at shoot tips and here a proportion of side shoots should be left unpruned. Summer pruning is advisable on restricted trees such as cordons for details see Pears (T.17).

Very few varieties are self fertile and at least two sorts should be planted to ensure satisfactory crops. Good combinations are Cox's Orange Pippin with Laxton's Fortune and Winston with the cooker Lord Derby. Seek expert advice on pears if in doubt. Some discerning housewives like apples which break down or fruit on cooking, in this case Emmeth Early, Lane's Prince Albert or Monarch may be planted. For those wanting one which stays firm on cooking Bramley's Seedling should be chosen.

Blackberries—In modern gardens where space is limited the best returns in fruit growing are often with the cultivated forms of blackberries and loganberries. Plant at least 10–12 ft. apart against fences and train on wires set 3 ft. 5 ft. and 6 ft. above soil level.

Cropping is dependent on manual treatment as all are heavy feeders. When planting enrich the site with manure, compost or leafsoil afterwards mulch the surface with one of them. Annually the ground should be topdressed with compost supplemented with a nitrogenous manure like sulphate of ammonia, chicken manure or dried blood. Also apply sulphate of potash at 1 oz. per sq. yard. Such treatment will show excellent results and as a bonus normally ensures a prize at any local Show. After planting do not lack courage to cut back all growths to within a foot of ground level and keep the soil moist throughout the growing season.

Cherries—Sweet cherries are unsuited to most gardens. The trees become too large and must be planted in selected pairs to fruit satisfactorily as all varieties are self sterile. Large wall spaces are ideal for fan trees, as the fruit can then be protected from birds by the use of nets. Pinch side shoots on fans to four leaves in July. Further pruning details being as for plums. Expert advice is essential to ensure that suitable varieties are grown together, the factors involved being

complicated. Early Rivers with Bigarreau Schrecken and Merton Heart with Waterloo are good combinations.

Currants Black—These are perhaps the most valuable of all hardy fruits and bushes will give up to 10 lb. and more of currants with correct treatment. Plant from November to February preferably autumn at 5 ft. square on clean heavily manured ground. In the following spring it is important to cut all the shoots to within 3 ins. of ground level in order to encourage strong new growth.

Poor results with this fruit are often due to keeping old or worn out bushes when the cropping life is past which for blackcurrants is around 10 years. Another reason is the lack of feeding. Each spring bushes should be mulched with compost supplemented with a nitrogenous fertilizer like sulphate of ammonia at 1 oz. per sq. yard and superphosphate at double this rate.

On established bushes prune preferably after fruiting or in winter retaining strong young wood and cutting out older shoots where possible from ground level. If necessary alternate bushes can be cut down completely every year to maintain vigour as the bulk of the crop is always borne on young wood. Increase by 8 in. cuttings of one year old wood taken in late September from healthy bushes. Remove lower leaves and insert firmly with one bud above ground. Good varieties Boskoop Giant, Wellington XXX.

Currants Red and White—One or two well grown bushes are usually sufficient for the average household. Plant between November and March at a minimum of 5 ft. square on well manured ground and mulch each spring. Supplement with fertilisers if necessary, potash being particularly important in the form of sulphate of potash at 1 oz. per sq. yd. in February. Can be grown as cordons or fans against walls or fences on which the pinching of young side shoots to four leaves in mid June is essential. Winter pruning of all types simply involves cutting side shoots to one bud and tip pruning branch leaders.

Propagate by 12 in. cuttings of young shoots in late September inserted to half their length with all buds removed except the top four. This enables the bush to be grown on a leg. A permanent framework of branches is then developed as in contrast to the black currant fruit is borne on spurs on the old wood. Good varieties Laxton's No. 1, White Grape.

Damson—See Plums

Figs—A warm south wall is usually essential. Brown Turkey being one of the few reliable outdoor varieties. Plant in a brick or concrete trough (with drainage holes) about 2½ ft. wide, 5 ft. long and 2½ ft. deep so that the root run is restricted. This will curb excessive growth (which otherwise is difficult to control) and encourage fruiting.

Plant in March for preference to avoid frost injury to young shoots and then train fan wise. A rich soil is not essential. Figs visible as such in the autumn will never over winter and should be rubbed out. Those the size of a pea and less at the tips of short well ripened shoots on the other hand are the potential crop for the following year and should be covered in severe weather to avoid frost damage. To encourage the formation of these embryo fruits pinch young shoots back to the fifth leaf in late August. Winter prune in March removing any wood that is frosted, overcrowded or worn out. Growth should be spaced at about 1 ft. Apply a spring mulch and water freely when required to avoid premature fruit drop.

Gooseberries—Need conditions and spacing very similar to red currants, but with rather more moisture to ensure ample new wood, as this bears fruit as well as the older wood. Apply sulphate of ammonia and sulphate of potash annually in late February or March at 1 oz. per sq. yd. of each in addition to mulching. Can also be grown as cordons, etc. as for red currants. Pruning is also similar though not quite so severe as the young wood is productive of fruit. Cuttings are more difficult to root and for best results should

be taken in mid September again as for red currants. Good varieties: Lancer, Leveller, Winham's Industry.

Grapes—Outdoor vines should be grown against a warm south or south west facing wall. With good cultivation the grapes should then ripen successfully providing suitable varieties are chosen. In preparing the vine ensure that it is well drained and break up the soil to a depth of about 2 ft. Add bone meal to the top few inches at 3-4 oz per sq yd and incorporate mortar rubble particularly on the heavier soils. Do not dig in any manure except on poor light soils but always apply some as a mulch after planting repeating this every spring. On poor hungry soils the importation of some fibrous loam is advisable where possible.

Plant in November or failing this before early March with the stem about 8-9 in away from the wall. Firm well and then wait a further two months before tying to any wires or stakes in case of soil sinkage. Cut the vine back in winter to well ripened wood and to just above a bud. The training of subsequent growth will then depend on the space available single and double cordons being the most convenient. Unwanted shoots should be pinched at about 2 ft in summer and leading shoots carefully tied in to wire or bamboo supports. The following winter (December) prune leading shoots back a well ripened wood so as to leave 3-4 ft of new growth. Then cut all laterals hard back to one bud. In spring remove young side shoots to one at each bud stop laterals at about 12 in and pinch out sub laterals that may develop to the first leaf. Do not allow any crop to develop except perhaps one bunch if growth is adequate, others should be pinched off. As fruit develops thinning should be done as required. Winter prune as before and then in the third summer four or five bunches of grapes can be allowed if the vine is healthy the crop then increasing annually. Shoots carrying bunches should be pinched to two leaves beyond the bunch. Winter pruning is repeated each year as already described. Sour top soil should be carefully removed when necessary and replaced with good loam while the vine is dormant. Good varieties: Black Hamburg and Foster's Seedling.

Loganberries—A very popular hybrid berry which should be treated as for blackberries. A thornless form is now available. Suitable for a north wall.

Medlars—A tree of spreading habit the peculiar fruits of which are best used for jelly before they are fully ripened. Most soils are suitable and no pruning is needed except to keep in shape.

Nectarines—A fruit very closely allied to the peach but with a richer flavour and needing rather more warmth. The skin is smooth, as distinct from the hairiness of the peach. For full details see Peach.

Nuts—The most important kinds grown are cobnuts the closely related filberts, and walnuts but none of these is cultivated to any great extent. The two former kinds flower very early in February and are therefore predisposed to frost damage similarly the young shoots of walnuts are easily injured by spring frosts, and all are therefore inadvisable for frosty areas.

Cobnuts and filberts—Highly developed forms of the ordinary hazel nut. The nut of a cob is only partially covered by the husk whereas a filbert is completely enclosed by it this being the essential difference between the two. Will grow on most soils including the poorer ones and spacing should be about 15 ft., choosing sites sheltered from the colder winds. Plant during the autumn. Prune established bushes in March, cutting back shoots that have borne nuts to two or three buds. Strong young shoots are cut back to a catkin near their base and the weaker ones are left untouched. In August any strong new side growths are pruned off—that is, broken off—and left hanging until the March pruning. Gather the nuts as they fall and allow to dry. Then store

in jars for Christmas use, packing salt and coconut fibre between each layer of nuts.

Walnuts—Special grafted varieties are now available which produce early crops compared with the unreliable seedling trees that used to be planted. Plant between October and March and water well in spring and summer. Do not prune as walnuts bleed badly. Gather nuts in mid-July for pickling. For storing allow to drop naturally and remove outer husk immediately scrubbing the shell clean and then drying thoroughly. The shells can be bleached if necessary before storing. The nuts are for cob above.

Peaches—This fruit along with its close ally the nectarine is best grown against a warm south or south west wall but two varieties of peach, Peregrine and more particularly Rochester will succeed as bushes in the open in southern England. The fan trained peach is one of the most difficult trees to keep in order as sufficient new shoots must be retained annually to replace old wood. This is essential as it is only the new vigorous year's shoots which bear fruit. Badly placed shoots are rubbed out when only an inch long and the principle is to allow one young replacement shoot to develop near the base of each fruiting shoot pruning back to the former and tying it in as soon as all fruit has been picked. Other shoots may be used to extend the fan where space allows or to replace any branches or parts of them which may have become worn out. Other unwanted shoots are bound to arise during early summer and these are either removed immediately or pinched to three leaves and then removed when ripening in late summer. Those shoots retained are spaced at about 4 in apart.

Most peaches are self fertile but hand pollinating on sunny days can improve the set. Excessive feeding should be avoided varying this according to each tree's performance but as a general rule a surface mulch of well rotted manure or compost should always be given each spring together with sulphate of potash at 1-1 oz per sq yd. Prick over and rake off top soil and replace with good loam every few years. Never allow the sub soil to dry out—this can quickly occur against warm walls—and water thoroughly when doing so to ensure an even distribution of moisture. On the other hand, drainage must be satisfactory to avoid waterlogging.

There are numerous other essential operations in the growing of trained peach trees (for example fruit thinning) and it is impossible to deal with these adequately in brief notes. Would be growers should therefore seek expert advice and obtain literature dealing specifically with the crop rather than risk disappointment. Good varieties for outside wall training include *Peregrine*, *Peregrine Belle*, *Nectarine*, *Early Rivers*, *Lord Napier*.

Pears—The requirements for pears are similar to those for apples but the necessity for adequate summer and autumn warmth rules out many varieties for northern areas. In these less-favoured localities enquire which varieties do succeed and where possible make use of a warm south facing wall. Protection from wind is very important, particularly from the cold easterlies of spring. Many soil types grow pears satisfactorily providing drainage is good and the trees are looked after. Plant as for apples. Fertiliser requirements are also similar once cropping commences, except that pears may require a little more nitrogen.

Pruning (winter) is comparatively simple, the spur pruning given for apples suiting all except a very few pears. Initial shaping is essential, cutting the stronger shoots selected to form branches by about half their length and keeping the centre of the tree open. For cordons and other restricted forms of tree, to which pears lend themselves particularly well summer pruning is advisable. This involves shortening all young shoots more than 10 in in length to about 5 in from the base. Do this when the base of such shoots is hardening and turning brown in colour, usually late July-early August. Pruned shoots may then be further reduced in winter. Such summer treatment may also be given to trained apple trees with advantage during August.

Only a few pears are self fertile and Con

ference is the most reliable if only one tree can be planted. Good pollinating pairings include Laxton's Superb with Doyenné du Comice and Conference with Williams Bon Chrétien. Early varieties should be picked a little before ripening and used quickly.

Plums—This general term includes gages and damsons. Numerous varieties are easy to grow but are unsuited to small gardens because of the amount of space required. Unlike apples and pears there are no dwarfing rootstocks and a minimum spacing of 14 ft should be allowed for growing the trees as half standards or fan trained against a south or west wall. Flowering is during April and frost damage can be serious in some seasons. Plant preferably in the autumn and by early March at the latest, using no manure unless soil is distinctly poor. Young trees should be staked during their early years and must not be allowed to rub against the support.

Pruning should be reduced to a minimum as the spores of silver leaf disease gain entry through wounds such as pruning cuts and stake rubs. Shorten branch leaders on young trees just as buds are bursting but on older trees prune only when branches become overcrowded. Do this between June and August when the risk of silver leaf is at a minimum. Cut cleanly and coat the wounds thoroughly with a bituminous paint. Treat broken branches similarly immediately they are noticed. Trees fruiting heavily should have the branches supported and the fruit thinned in late June. Side shoots on fans must be cut to four to five leaves in late June and reduced still further following picking if necessary. Feed cropping trees regularly to encourage new growth by mulching the soil generously with manure or compost or leafmould in early spring. Some varieties are self fertile including Victoria, Oullins Golden Gage and Merryweather Damson.

A WELL-PLANTED TREE illustrating (A) a good method of tying and (B) sacking firmly secured with sacking around the trunk and held with stout cord.

Raspberries—These are an ideal fruit for the small garden, but because of virus disease always buy certified canes from a fruit nursery. Plant between November and March on clean, well-manured ground, allowing 18 in between canes and 6 ft between rows. After planting prune

each cane back to 12 in. Do not attempt to crop them in their first year or the production of young canes for the following year's fruit will suffer.

A semi-shaded position will answer but full sun is preferable for quality fruit. New canes should be looped with string to a post and wire fence and later tied individually to each wire when fully hardened. Space them at about 4 in and remove any weak or diseased canes at ground level. In late February cut each cane to just above the top wire which is usually 5-6 ft high. This removes any damaged tips and may encourage fruiting over a longer length of cane. In the second summer a fair crop should result and netting against birds is essential. Regular watering is imperative in dry weather and spring and summer mulches of well rotted manure or compost should always be applied. Supplement this in March with nitrogen and potash (fertilisers) if required, this depending on how well the ground was manured before planting. After fruiting cut out all old canes and tie in the new ones as already described. Malling Promise and Lloyd George are good varieties.

For autumn fruiting varieties prune all canes to the ground in late February and tie in the best during the summer for cropping in September-October. September is a good variety and Lloyd George can also be used.

Strawberries—This is the one fruit that should be included in the vegetable garden. Fresh ground can then be used regularly for establishing new beds. Plants more than two years old are seldom profitable and the best fruit is always picked from healthy one year olds planted the previous August or September. Runners put in later than early October should be deblossomed the following spring the reward being a much heavier crop in the second year. This wastes ground, however and early planting is preferable on all counts. Prepare the ground well in advance of planting and dig in plenty of well rotted manure or compost or both as this is the key to success.

Because of virus diseases order certified plants from a fruit nursery and burn any unhealthy ones in old beds before planting. Insert firmly with the base of the crown of each plant just at soil level and refirm after winter frosts. Space at 20 in in rows and 2 ft 6 in between rows (3 ft if possible). A mulch of rotted manure or compost is beneficial each autumn together with an application of sulphate of potash at 1 oz per sq yd. In the spring growth can be encouraged by feeding with Maxicrop, quick acting nitro genous fertilisers should normally be avoided.

During flowering cover the plants where possible to guard against frost damage reducing the crop. Keep the ground weed free and remove runners regularly, a few plants should always be grown away from the main bed, deblossomed and kept purely for runner production, as this then helps to reduce the spread of virus. Ruthlessly burn any plant that remains stunted including its runners as this is usually a symptom of virus disease. When the young fruits are just forming spread clean straw underneath them to avoid splashing from the soil, it is a mistake to do this too early as it increases the risk of frost damage. Net the fruit against birds and remove any rotting specimens when picking.

After fruiting remove and burn all old foliage, weeds and straw and feed as already described. Plant a percentage of new vigorous runners each year on fresh ground at the same time burning the old ones they are replacing. For flavour the best variety is still Royal Sovereign of which healthy stocks are available.

Alpine strawberries require similar treatment preferably with a semi shaded position and should be raised from seed. Perpetual fruiting types continue fruiting on and off well into the autumn and should be treated as for ordinary varieties. In all cases cloches can be used from late February onwards to obtain early fruit.

THE VEGETABLE GARDEN

The Small Plot—For some years the trend in gardening has been decidedly towards growing ornamental plants vegetables have been neglected. This has gone so far that in many instances the vegetable plot has been done away with altogether. As a result throughout the summer housewives have faced the high cost of buying even such easily grown crops as lettuce or gongers without them when supplies are short. A further factor promoting a return to home gardening has been the information now available on the toxic properties of some chemicals used freely in commercial horticulture.

To avoid these problems even a small piece of ground can be used to excellent purpose if first manured and dug over thoroughly. The ideal site is an open sunny position sheltered from cold winds with the soil a deep rich loam well supplied with humus obviously few gardens have such a site but much can be done in most circumstances. Once the ground is ready a few sowings of radishes can be made and lettuce

crops and a suitable succession. The land can be divided into four plots, one is used for the more or less permanent crops, such as asparagus, rhubarb and globe artichokes, and the other three will provide a rotation. This is used to stop any group of vegetables being grown on the same land more than once in every three years so preventing the carry-over of some pests and diseases and providing for a full use of the manures in the soil as different groups of vegetables need more of some nutrients than others. It also allows the clearance of one section to enable winter digging and manuring to be carried out. On this freshly manured plot peas, beans, onions, leeks and lettuces all revelling in rich ground, should be grown. The next plot manured for the previous crop can be used for root crops—early potatoes, carrots, parsnips and beet. A light dressing of artificial fertiliser such as National Growmore should be applied before sowing. On the third plot the green vegetables should be grown a dressing of fertilisers is desirable and lime should also be applied.

In the following season the root crops can be

DOUBLE DIGGING—A sound cultural practice. A trench 2 ft. wide and the depth of a spade is taken out at A and placed as shown. The bottom of trench A is then forked up and filled in with soil from B and the process repeated with C and D etc. In double digging the sub-soil is *always* left on the bottom and never brought to the surface.

cropped throughout the summer. Other vegetables worthy of consideration are the sowing of spinach and onions grown from sets. Of course in the small plot priority should be given to providing a fresh supply of herbs like sage, thyme, chives, parsley and a clump or two of rhubarb.

General Cultivation—On a new site soil preparation is important as all vegetables do best on ground in good heart. The land should be dug two spits deep (double digging) and for this purpose the plot is divided into two longitudinally and a trench 2 ft. wide and 10 in. deep is dug out as illustrated above. The sub-soil at the bottom of the trench is then broken up and manure or compost added (or turf if grassland is being dug). The next strip is then dealt with in a similar manner and the process continued down the plot to the last trench which is finally filled in with the loose soil from the first trench. Double digging is not necessary every year and single digging carried out in a similar way without breaking up the second spit or sometimes a light forking over is sufficient.

Clay soils can be lightened by adding heavy dressings of peat or compost and coarse materials like ashes and road grit. Sandy soils are also improved by addition of humus in this case to conserve moisture. These soils are less fertile than clay ones but are easier to cultivate, are warmer and crop earlier. In both cases the addition of lime is only desirable if the ground is too acid; most vegetables it should be noted do best on slightly acidic soils not alkaline ones. If any doubt exists then it is always best not to lime.

The lay out with vegetables must be designed to provide a succession through the year and to utilise the full capacity of the ground by catch

grown on the plot which was manured the previous year and the brassicas grown on the land vacated by the root crops. The plot on which the brassicas were growing is double dug and manured ready for the peas, beans and onions. A system of this type proves very satisfactory but numerous variations can be devised and it is really a matter for the gardener to decide his best method. The growing of maincrop potatoes will complicate the system, as a large area is usually required. They are better grown separately in another part of the vegetable garden.

Usually it is wise to have a small piece of ground available for a nursery bed. This should be of good fine soil in which seeds can be sown to supply the main plot. In all cases seed should be sown very thinly to prevent the necessity for much pricking out and a slug killer is often a wise precaution to use before sowing. Sowing dates, as given, are mainly for growers in the South. In the North sowing dates in spring will be generally two weeks or more later and autumn operations the same amount earlier. Any gardener must adjust his work to suit local conditions of soil and climate and this knowledge is only gained by experience of the particular area.

General cleanliness in the vegetable garden is at all times desirable. Weeds and rubbish only harbour pests and diseases, and the hoe should be busy whenever possible. Waste material can be utilised in that essential of the modern garden—the compost heap. See *Manures and Fertilisers* for description.

Frames and Cloches—The gardener is able to extend the season of many crops by protecting them under frames and cloches. This is particu-

larly useful where spring or early autumn frosts are prevalent. The use of frames is limited as they are in a fixed position but nevertheless they are very useful for obtaining out of season salad crops especially if they are heated by electricity or a hot bed.

Cloches have the advantage of mobility and can be used on a number of crops in succession. Essentially each is a number of pieces of glass in a tent or barn shape held together by wire. Pattern size and height vary according to the crop to be covered and the manufacturer's design. A good cloche should be of simple design, rigid and capable of standing up to ordinary winds easily transported and well ventilated.

The low barn cloche is probably the most economical type. This is 28 in wide and 13 in

to water. Rain seeping under the cloches and a spray directed over them occasionally will provide enough for the crop in normal weather on dry sandy soils it may be necessary to spray over the cloches more often. A mulch of compost is also very useful to help retain water.

Dwarf varieties should be used or growing under cloches although methods of raising the cloches another foot or so have been devised and are on the market which allow the use of taller growing varieties. Many different vegetables can be helped to some extent in the early stages besides those crops which can be grown entirely under cloches the grower must decide what crops he needs and at a rotation to cover as many crops as possible with the cloches available. This is mainly a matter of experience but books on the

BARN

LOW BARN

PLASTIC

TYPES OF CLOCHES—The most popular is the barn cloche with 12 in sides it will cover strawberries and peas and beans in their early stages. The low barn will accommodate three rows of lettuce in winter and cucumbers in the summer. Plastic cloches are growing in popularity especially those patterns using toughened plastic and have some decided advantages over glass ones.

high when erected and will allow two rows of lettuce to be grown with an intercrop of another vegetable. The large barn or barn cloche of similar design but with 12 in. side is 19 in high in the centre enabling taller crops *e.g.* peas and dwarf beans, to be grown on almost to maturity. The tomato cloche has sides 24 in square and a basal width of 26 in. Many others of various shapes and sizes are offered the amateur should buy to suit his own requirements. Other materials have been tried instead of glass with varying success. Plastic cloches are on the market but their lightness entails very safe anchoring and at the moment glass still seems to be the best material in most instances.

Gardening under cloches obviously is a subject too large to be dealt with in a few sentences and the reader would be well advised to refer to one of the books mentioned in the bibliography for fuller information. A few of the main points are mentioned here and also under the individual crops.

Cloche cultivation is an intensive method of production, and this means that the land must be well cultivated and manured to ensure good quality crops at all times. About ten days before crops are sown or planted the cloches should be put in the position where they are to be used, to warm the soil. The crop is sometimes sown a month before the normal date and this prewarming ensures that the soil can be cultivated to a good tilth as well as giving the plants a good start. Watering is a problem that often bothers the amateur. Provided the soil is well watered at sowing time, there should be no need to decloche

subject will suggest many variations that can be tried. Intercropping with quick maturing crops can also be practised. As instances radish or mustard and cress can be cropped between two rows of lettuce or a row of cos lettuce can be grown between two rows of cabbage lettuce.

It must be remembered that the glass of cloches will need cleaning from time to time the crop still needs the maximum light available although shading of certain crops may be necessary in hot sun.

Artichokes—Two different plants are grown as artichokes. One the Jerusalem artichoke (*Helianthus tuberosus*) is related to the sunflower and is grown for its tuberous roots which are second in food value only to the potato. It will grow in poor soil but amply repays good cultivation, and may be placed at the more exposed end of the vegetable plot as a windbreak and screen. Tubers should be planted during February or March on well manured ground in drills 4-6 in. deep and 2 ft 6 in apart with 15 in between the tubers. Hoe frequently during the summer and cut the stalks down in early winter. The tubers may then be lifted and stored or better dug as required, reserving a number for replanting the following February.

The other type the globe artichoke (*Cynara scolymus*) is often grown as an ornamental plant but is esteemed as a vegetable for its young fleshy flower heads, which must be cut before the scales begin to open, after which they become hard and unpalatable. A deep rich well manured soil is

required and after planting in early spring in rows 4 ft apart with 2 ft between the plants a crop of manure much is beneficial. A good crop may be expected for five or six years provided an annual dressing of manure is applied. After this time they should be replaced by young suckers planted in a fresh position. A covering of straw or bracken on the crowns is advisable during winter.

Asparagus—This will grow on most types of soil provided that drainage is good and that plenty of organic matter is available. The site for the asparagus bed should be double dug in the autumn prior to planting and a generous dressing of about half a barrow load of manure per square yard incorporated. Crowns up to three years old may be bought but it is found that one year old crowns give the best results. Plants may be obtained cheaply by sowing seed in late March in drills 1½ in deep and 18 in apart and thinning the seedlings to 4 in apart. It is thought that male plants produce more stalks of better quality than female plants but at present no supplies of male crowns alone are available.

Planting may be on the single-row system or the wide bed system. In the single-row system crowns are planted 18 in. apart in rows 4½ ft apart. The wide bed system consists of 5 ft beds, with three rows of crowns 15 in apart each way and 2 ft between each bed. Planting is best done during April and the plants are placed in a trench 8 in deep and 1 ft wide with a slight ridge at the base, and covered with 3 in. of soil. The remaining soil is worked in during the summer. The roots should never be allowed to dry out.

The following March 2 oz per sq yd of sulphate of ammonia should be applied in subsequent years 3 oz per sq yd of National Growmore applied at the same time followed by 2 oz per sq yd of sulphate of ammonia in June, after cutting can be used. Salt as a fertiliser is not recommended nowadays. An annual dressing of manure or compost in November is desirable.

No cutting should be done for the first two years after planting and only a light cut taken in the third year. After this a six to eight-week season beginning in early May is usual. The spears should be cut when about 4 in above soil level and severed about 2 or 3 in below the soil giving an overall length of 6-7 in. The fronds should be cut in October before the seeds drop but not during the summer as the plant is weakened. Weeds should be kept down and in the autumn the plant may be earthed up.

Varieties: *Connoyer's Colossal* and *Kidner's Pedigree*.

Beans Three types are commonly grown, as follows:

Broad Beans are the hardest and can, in warm gardens be sown during autumn to obtain an early crop. Little is gained by this as a rule and sowing in well manured ground in February when the soil is frost free with successional sowings during March and April is generally better in most gardens. The soil is broken down, finely raked and the seed sown 9 in. apart in drills 3 in. deep with 18 in. between each row. If double rows are sown 10 in. should be left between the rows and 2 ft between each pair of rows. Staking may be necessary. Plants from sowings under glass or under cloches in January may be used to obtain an earlier crop. The cloches should be removed in March and a further crop sown and re-clothed.

Black aphid was a serious pest but is now easily checked by pinching out the young tips and applying malathion or lindane as soon as any are seen. The pods may be used before the beans are fully developed and sliced as are runner beans, but normally they are picked when the beans are well formed but not tough.

Varieties: *Aquadulce* and *Green Masterpiece*.

Dwarf Beans (which include French, Kidney and Haricot Beans) may be either used as young pods in a similar manner to runner beans or ripened in the pod for winter use. A rich well manured soil gives the best results, and seeds sown during the first week in May 2 in deep and

6 in apart in drills 18 in. apart, may be followed by a second sowing at the end of May. The young plants should be thinned out to 1 ft apart and small twigs used to stake them. If sown earlier frost damage may occur. Seeds may also be sown in the greenhouse and the seedlings transplanted or sown under cloches in the last week in March provided the soil has been prewarmed.

The plants as long as the pods are picked over frequently will continue to bear until the frosts. A little liquid manure will be beneficial during the summer. A late sowing in July clothed in September will continue the season into the autumn.

If required for winter use (Haricot varieties) certain plants should be left unpicked and the pods allowed to ripen on the plants. They should not be picked green. If winter when frosts come the plants should be pulled up and dried in a shed.

Varieties: *The Prince* (Cliche) *Masterpiece* and *Comtesse de Chambord* (Haricot).

Runner Beans are the most popular type and can be grown in two ways either without stakes in which case the tips of main and side shoots are regularly pinched out to make a bushy dwarf plant a method often used by farmers or staked with cross poles allowing the plants to climb to the tops of the poles before pinching. Seed is sown from early May (mid April under cloches) until late June depending on the danger of frost. Usually a double row with drills 15 in apart and with seeds 3 in deep and 6 in. apart in the rows alternate plants being removed later.

Staking should be done as soon as the first pair of leaves unfolds and a surface mulch is then applied. If the beans are to be dwarfed the rows should be about 18 in. or 2 ft apart and pinching may be required about once a week. A good, well manured soil is essential and plenty of moisture is required. The flowers may fail to set in dry weather and an evening spray of water is helpful in preventing this running off. Harvesting should be carried out regularly while the pods are young before the seeds swell. Older pods are stringy and seldom worth eating.

Varieties: *White Bear* (white flowered heavy cropper) and *Streamline*.

Beetroot—From mid April onwards varieties of beet may be sown on soil that has not recently been manured but is in good heart on freshly manured soils coarse forked roots subject to cracking occur. If in poor condition a light dressing of a complete fertiliser should be given before sowing. Sow in drills 1 in. deep and 12 in. apart and make a first thinning to 4 in. apart when the first rough leaf appears and a second later leaving 9 in. between the plants. Transplanting is inadvisable. Early roots for summer pulling may be obtained from a sowing of a *Globe* type in mid April and the main sowing should be made during May or early June for the winter supply. A sowing under cloches in late February will provide roots for pulling in late May.

On a heavy soil the oval rooted types are best but on a lighter soil the long rooted types may be used. A sowing in late July of the *Globe* type will provide beet for use at the end of winter. Salad beet from early sowings may be pulled as required. The main crop should be allowed to mature and is lifted in October before the roots become woody and tough. Any damaged roots should not be stored. Twist off the tops just above the roots shake the soil from the roots and store in boxes of sand or peat in a frost-free shed. If clamped outside straw and a thick layer of soil should be used. If frost reaches them they are spoiled.

Varieties: *Globe*—*Detroit Red* *Red Globe*, and *Crimson Globe* oval—*Cobham Early* long—*Cheltenham Green Top*.

Sugar beet is similar but is white not red fleshed, and is mainly a farm crop if desired it may be grown in a similar manner. Care should be taken in hoeing all beet crops to avoid damage to the small surface roots which feed the swollen rootstock.

Borecole.—See Kale.

Brassica.—A generic name of vegetables usually known to gardeners as greens. This group

includes brussels sprouts cabbages cauliflowers kale turnips kohlrabi broccoli and courgette. As they are all related similar soil and cultural treatment is needed and many pests and diseases are common to them. Each is dealt with under a separate heading.

Broccoli.—See Cauliflower

Brussels Sprouts—Young plants from seed sown thinly in a nursery seed bed during mid-March can be transplanted during May or June. The soil should be firm well drained in good heart and contain adequate lime some manure preferably having been dug in during the winter a supplementary dressing of 2 oz superphosphate and 1 oz of sulphate of potash per square yard is given before planting. The young plants should be set out 3 ft apart both ways planted firmly and watered in thoroughly. Regular hoeing is necessary and about a month after planting a little soil should be drawn round the stems.

If growth seems weak a top dressing of nitro-chalk should be given and this repeated in early September. As the lower leaves yellow cut them off and gather the sprouts as they mature picking from the bottom of the stem. Where space is available a succession of sowings from March to June can be made to lengthen the crop-ping period.

Club root the worst disease of brassicas is kept in check by only using well limed well-drained soil and dipping the roots in 4% calomel before planting and cabbage root fly a frequent insect pest by using Indane.

Varieties early—Cambridge No. 1 mid-season—Rous Lench and Triumph (dark foliage distinct).

Cabbage—Sowings in March and April for summer use in May or June for winter use and in late July or August for spring use will give a succession of cabbages all the year round. Seed is sown thinly in a nursery bed of well limed, limed soil clear of weeds in drills $\frac{1}{2}$ in deep and 6 in apart and the seedlings dusted with Indane to check flea beetle attack (prevalent with all brassica seedlings). All cabbages are gross feeders and a well drained soil in good heart with adequate lime is required.

Spring cabbage should be sown during late July (north) and August (south). If sown too early the plants may bolt without making a heart. The young plants are set out in mid-September 18 in apart and with 18 in between the rows if for hearting or 9 in apart with 18 in between the rows in which case the alternate plants are cut for spring greens. On a heavy soil ridging along the rows of plants keeps the soil round the roots drained and helps to prevent loosening by frosts. In cold districts cloches may be used with advantage to help plants through the winter. In early March a dressing of 1 oz per sq yd of sulphate of ammonia or nitro chalk is a good stimulant.

Seed of summer and autumn cabbage is sown in March and April and planted during late May and June 18 in to 2 ft each way between the plants depending on the variety. The plants should be thoroughly watered both before and after transplanting. A top dressing of 1 oz per sq yd nitro-chalk may be given if required.

Winter cabbage maturing from October to February from sowings during May and early June are set out 2 ft apart each way in July or early August usually on ground which has been cropped with early potatoes or peas. No nitrogen fertiliser should be given late in the season as soft growth liable to frost damage is encouraged. A balanced fertiliser such as National Growmore may be used if needed. When the stalks of cabbage are left standing over winter a common practice is to cut across the tops to obtain bunches of leaves for use as greens during early spring.

Savoy cabbages mature during winter and early spring from seed sown in May. Seedlings are transplanted in late July and early August on to land manured for the previous crop to which a dressing of 2 oz superphosphate and 1 oz sulphate of potash per sq yd has been applied. The young plants should be set out 2 ft apart each way they are exceptionally hardy and

should be grown in every garden in case of a hard winter.

Varieties Spring sowing—autumn cutting Greyhound (early) Wimmingstradt autumn sowing—spring cutting April Wheeler's Imperial Savoy Ormskirke Late Green.

Red cabbage is slow to mature plants from sowings in August are transplanted 6 in each way in autumn and set out in early spring 18 in each way. They are ready to cut in late summer.

Cardoon (*Cynara cardunculus*)—Closely related to the globe artichoke and grown for the blanched hearts. Seed is sown in trenches 18 in wide and 1 ft deep 3 in of manure is worked into the bottom soil and covered with 3 in of fine soil. Three or four seeds are dibbled in every 18 in and covered with a flower pot till viable and then thinned out leaving one strong seedling at each station. Protection from sun and late frosts is provided by twigs over the trench and continuous watering is given during the summer.

On a fine day in September the plants are blanched by tying the leaves together and covering with dry hay 3 in thick kept in position by raffia and earthed up in the same way as celery. Blanching is completed in about a month.

Carrots—A light well drained soil enriched with decayed organic matter is suitable for carrots. No fresh manure should be given but a light dressing of National Growmore fertiliser can be applied prior to sowing. The surface is left rough until sowing time and then broken down to a fine tilth. The first sowing is made in early April in drills $\frac{1}{2}$ in deep and 12 in apart and a succession is obtained by sowing at intervals of a month until the end of July.

On heavy unfavourable soils stump rooted varieties are best grown long rooted varieties needing a light soil. Thin out the stump rooted varieties to 4 in apart and the longer varieties to 6 in. Thinnings should be removed and the soil pressed firmly back to minimise damage by carrot fly. The early sowings are pulled as required but the later sowings for winter use should be lifted in October and stored in slightly damp sand in a frost proof shed or clamped in the open.

Frames and cloches are sometimes used to obtain early and late carrots. Seed of a quick growing variety such as Amsterdam Forcing or Early Nantes sown in late January under cloches or in frames will provide an early crop. The same varieties sown in frames or cloches in early August will provide young carrots for the autumn. Carrot fly is a bad pest especially on light soils the seedlings should be dusted in the rows with Indane when 2-4 in high to prevent the flies from egg laying.

Varieties globular—Early Gem stump rooted—French Short Horn intermediate—Amsterdam Forcing and Early Nantes long—St Valery and Long Red Surry.

Catch Crops—A term used for quick growing crops interplanted between rows of other crops. Radishes between rows of broad beans and lettuce between celery rows provide examples. In this way the best use of a limited amount of land can be made.

Cauliflower—Broccoli is for all practical purposes a hardy winter cauliflower. Seed is sown $\frac{1}{2}$ in deep in a nursery bed from mid-April to mid-May depending on the variety and transplanted during June and July on to firm soil well manured for the previous crop. The plants are set out 2 ft apart each way 2 oz superphosphate and $\frac{1}{2}$ oz of sulphate of potash per square yard may be hoed in before transplanting. No nitrogenous manure should be given late in the year.

Varieties cauliflower—Snowball (summer) Majestic (autumn) Broccoli—Snow's Winter White (winter) St George (early spring) Sprouting broccoli—Nine Star Perennial (a many headed sort).

Sprouting broccoli is very hardy has a more leafy head and is cultivated in the same way. Purple and green sprouting sorts are grown also. Summer cauliflowers require a soil which has been limed and manured during the winter. 1-2

oz per sq yd of superphosphate should be given before transplanting. An early sowing in frames in February or March will provide plants for cropping in June. These should be hardened off and planted in March or April from 18 to 24 in. square depending on the variety. Seed sown outdoors in April in drills $\frac{1}{2}$ in. deep will give plants for transplanting in May or June for cropping from late July onwards. If growth is slow a dressing of 1 oz per sq yd of sulphate of ammonia should be given. Leaves broken over the curds will help to prevent any damage from early frosts. Varieties given in previous paragraph.

Celeriac—A plant allied to celery grown for its edible root which resembles a turnip but has the flavour of celery. The stems are bitter to the taste and are not eaten. It is used in salads or boiled as other root crops.

Seed is sown in gentle heat in March and seedlings pricked out into seed boxes 2 in. apart each way. In June after hardening off the seedlings are planted out in shallow drills 18 in. apart leaving 12 in. between each plant in the row. Water freely during the summer and remove side shoots as they appear. Lift the roots in October or November and store in a frost-free shed.

Celery—Richly prepared ground is required. A trench 15 in. wide and 1 ft. deep is taken out, and manure worked into the bottom of the trench. The soil is then returned to within 3 in. of the ground level. Seed should be sown in early March at about 60° Fahrenheit and the seedlings pricked out in deep boxes 3 in. each way and gradually hardened off. Celery seed is very fine and care should be taken to cover it with only a fine layer of soil. If covered too deeply it may not germinate.

In late May or June set the plants out in staggered double rows 1 ft. apart with 10 in. between the plants and water them in. Frequent watering during the summer is required, and a light dressing of nitrate of soda will stimulate them if growth is poor. Before earthing up to blanch the plants, tie the stems loosely below the leaves and remove any suckers. Earthing up begins when the plants are about 15 in. high; the ground should be moist and the first earthing should only be slight. The second and third earthings at intervals of about three weeks should be more generous but should never reach higher than the base of the leaves and no earth should fall into the heart. For exhibition purposes brown paper collars may be tied round the stalks before earthing. The final earthing should cover all the stems right up to the leaves, and the soil should spread away neatly. In winter litter or bracken sown over the plants will help protect them from frost.

Celery fly is a serious pest and the brown leaf blisters should be pinched to kill the maggot inside and indene applied two or three times at fortnightly intervals. Slugs are a serious pest and must be eradicated. This can be done easily with slug pellets or a liquid formulation of Sluget.

Leaf spot, a seed-borne disease can be prevented by spraying with May & Baker's Bordeaux Mixture.

Varieties: white—Solid White, pink—Clayworth Prize Pink, red—Standard Bearer, self-blanching—Golden Self-Blanching.

Chicory—The young blanched growths are used in winter salads. Seeds are sown in drills 1 ft. apart in May; the young seedlings are thinned to 8 in. apart and grown on until October or November when they are lifted and the roots trimmed to 8 or 10 in. long. They are then planted in deep boxes in a moist sandy soil 5 in. apart each way leaving 1 in. above the soil surface and the boxes put in a warm greenhouse or cellar.

No light must reach the crowns. One method sometimes used is to cover the crowns with 6 in. of sand. When the blanched growths show through they are about 6 in. high and ready for cutting.

Chives—These are like small onions and the leaves are used for flavouring salads and soups.

They are easily grown in window boxes and town gardens. Bulbs can be planted in March 6 in. apart and divided when the clusters become too large.

Corn Salad or Lamb's Lettuce—Occasionally grown for the leaves, which are used in early spring salads. Seed sown from August to October will provide plants for winter and spring use.

Couve Tronchula—A large brassica known as Portugal cabbage, not generally suitable for smaller gardens. Seed is sown in March and the plants set out 2-3 ft. apart each way. The hearts may be cooked in the same way as cabbage.

Cress—An annual growing rapidly from seed and used as a salad when only the seed leaves have developed. Seed sown as required in boxes of light moist soil and covered with brown paper until germination when it is removed, will provide salad all the year round. The seed is merely pressed into the soil and the boxes kept moist. Cress may even be grown on damp flannel in a window.

Cucumber—The cucumber of the shops is grown as a specialist crop under glass. Temperatures of 50° Fahrenheit or more may be required and only occasionally are they grown by the amateur although cloche and frame culture is now popular.

Ridge cucumbers which are smaller and prickly outside may be grown outdoors in summer. Plants from seed sown singly in pots under glass can be planted during late May on ridges of good, well manured soil or alternatively sown on the ridges 1 in. deep at the same date. Water freely during the summer and cut the cucumbers while young to encourage further production.

If cloches are available greenhouse-raised cucumbers can be planted under them in mid April. Frame cucumbers are less hardy but young plants raised under glass can be planted under cloches in early May.

Varieties: ridge—King of the Ridge and Stockwood; ridge frame—Conqueror and Telegraph.

Endive—Used in winter or autumn salads. Seed is sown during April in drills 18 in. apart and the seedlings thinned to 12-15 in. apart. Sowings in June and August will provide a succession. A rich soil and plenty of moisture are the main requirements before eating blanching is necessary as the leaves are very bitter. This is achieved by tying the leaves loosely together and covering the plants with inverted flower pots (with the holes blocked) to exclude the light. Frost should be kept out by piling litter over the pots in winter. If cloches are used they can be coated inside with lime-wash to achieve the same effect. Alternatively plants may be lifted in October and blanched in darkened frames.

Varieties: summer—Green Curled; winter—Bavarian Broad Leaved.

Fennel—A perennial culinary herb used in fish sauces and salads. Blanched stems may also be cooked in the same way as celery. Seed is sown in drills 2 ft. apart in rich soil and the seedlings thinned to 18 in.

French Beans—See Dwarf Beans.

Garlic—One or two cloves planted in February 9 in. apart will provide ample garlic for salads, as only a little is required. After growth is complete in summer the bulbs can be lifted, dried and stored and some saved for replanting.

Haricot Beans—See Dwarf Beans.

Herbs—Many herbs are useful in small quantities for flavouring and garnishing, as well as being decorative. If possible, a separate herb garden should be made as a feature in the garden or they

may be used as edging plants. Perennial herbs of which borage, caraway, chamomile, chives, fennel, garlic, horseradish, lavender, mint, penny royal, marjoram, rosemary, rue, sage, tansy, tarragon, and thymes are the main types grown should be given a permanent position. Those grown as annuals—ansie, basil, coriander, dill, parsley, purslane, and summer savory—can be used as fill ins on the vegetable garden. Brick and cobble paths associate well with herbs imparting something of the character of the gardens of bygone days when herb gardens were considered one of the most important features.

Horseradish—A deep rooting perennial herb which appreciates a well manured moist soil. It is easily propagated from root cuttings and can become a nuisance as pieces of root left in the soil will make a new plant. Care should be taken to lift the complete root when digging it for use. Straight roots planted in spring with the crowns 6 in. below soil level and 1 ft. apart can be lifted for use in autumn, no further treatment is required apart from keeping weeds in check. Some of the roots should be kept for planting the following spring.

Kale—Very useful during a cold winter when other green vegetables are scarce because of its hardness. Seed sown in April or May will provide young plants for transplanting 18 in. apart each way in July or early August on to a site used for peas or early potatoes in good heart. A catch crop of lettuce can usually be taken from between the rows. The variety *Hungry Gap* is usually sown in rows 18 in. apart where it is to mature and thinned leaving 18 in. between the plants. There are many varieties which types are grown is a matter of personal preference. Varieties: *Cottager's* and *Hungry Gap*.

Kidney Beans—See *Dwarf Beans*.

Kohi Rabi—A brassica with a swollen stem base in flavour and appearance something between a turnip and a cabbage. Seeds sown in April in rows 1 ft. apart are thinned to 1 ft. apart in the rows and the swollen stem harvested when about the size of a tennis ball. If left to grow it becomes coarse.

Lamb's Lettuce—See *Corn Salad*.

Leeks—A vegetable which repays planting on a well manured soil. If they are to follow winter greens then manure or compost should be dug in after the previous crop is cleared. Leeks may be sown from early March to April in lines 8 in. apart on a prepared seed bed and the seedlings transplanted as land becomes available during June and July when about 6 in. high. Thinning in the seed bed should be unnecessary provided the sowing has been correct. The seedlings are set out 9 in. apart in rows 15 in. apart, a hole is made with a dibber and each seedling dropped in and watered thoroughly. No firming is needed, the watering should tighten the plants sufficiently. Alternatively drills 4 in. deep and 15 in. apart can be drawn out with a hoe and the plants put in 9 in. apart in the drills.

Regular hoeing is required and a feed of sulphate of ammonia (1 oz. per gallon of water) can be applied if in poor growth. In September a little earth should be drawn up around the roots which should by then be almost full grown. Leeks are very hardy and can be left in the soil until required for use.

Varieties: *Lyon* and *Musselburgh*.

Lettuce—Two main types are grown, cos lettuce, a summer crop with long straight leaves that curl inwards naturally or are tied in so that the heart is more or less blanched, and cabbage lettuce which are broad and spreading with round cabbage like hearts, and are grown to supply salad all the year round. Lettuce should be grown on ground manured during autumn or winter, dug and left rough till planting time when it is broken down and raked to a fine tilth.

This crop is a particularly valuable one for town gardens with restricted space. In these circumstances excellent returns can be had by raising seed indoors and pricking out the seedlings into small peat pots (Root o Pots). At this stage the plants can be grown on in a Stewart propagator which is simply a seed tray covered with a plastic hood and finally planted out of doors in their pots. The practice can be repeated or small sowings made in the open and seedlings thinned to 9 in. apart. Quick unchecked growth with plenty of moisture is essential on poor soils peat can be forked into the surface and an application of liquid Maxicrop made during the growing season.

Varieties: wide selection available of all types, small quick maturing sorts include *Little Gem* (*Sugar Cos*) and *Continuity*.

Maize—See *Sweet Corn*.

Marrows—Pumpkins, gourds, bush and trailing marrows all require similar treatment, plenty of sun and water and a rich soil, such as an old hot bed or compost heap which will provide a porous medium of humus. Seed can be sown singly in pots under glass in March or outdoors on the site in May. For cloches a bush variety must be used and greenhouse raised plants are cloched in mid April. Plant four or five seeds in groups about 6 in. apart and 1 in. deep and finally thin to two plants 15 in. apart. Protection from late frosts may be necessary. Water copiously and hoe regularly. Cut marrows when about 12 in. long to encourage further fruits. Some can be left until they are full size and cut before the frosts for storing in a dry frost proof place.

Varieties: bush—*Green Bush* and *White Bush*; trailing—*Long Green Trailing*.

Melons—Although usually a glasshouse crop, melons can be grown outdoors under cloches and in frames. Seed is sown under glass in April at 60° Fahrenheit and seedlings can be set out 3 ft. apart in early May. The soil should be manured generously and the seedlings planted on a mound of compost mixed with soil. The plants must be stopped at the fourth or fifth leaf to encourage laterals. Two can be selected to grow on and when 18 in. long pinched out to obtain sub laterals which will bear the fruit. The female flowers may require pollinating and on a sunny day a male flower or rabbit's tail can be used to transfer the pollen, as soon as the young fruits swell remove all but two or three per plant and pinch back the laterals bearing fruit to two leaves from the melon. A feed of dried blood once a week, with plenty of watering (though not saturation!) will help the developing fruits. Light shading may be necessary.

Varieties: *Dutch Net* and *Tiger*.

Mint—Easily grown from suckers in any soil. For winter use a few pieces can be planted in a frame. A number of varieties—*Apple Mint*, *Peppermint* and *Spearmint*—can be grown besides common mint.

Mushrooms—Growing mushrooms is really a specialist occupation. For the experimental amateur beds of composted stable manure are made up in a warm damp cellar or disused air raid shelter. Pieces of spawn are inserted when the temperature of the compost has dropped to about 70° Fahrenheit and the whole bed covered with an inch of inert sub soil. The air temperature should be from 60 to 70° Fahrenheit and in a few weeks mushrooms may appear. Full instructions will be given with the spawn but it is advisable to consult a text-book dealing with the culture as even for professional growers a crop is never certain.

Mustard—Grown exactly in the same way as cress but is ready two or three days earlier. If used together mustard seed should be sown two or three days after cress. Again it is the seed leaves which are eaten.

Onions—These respond well to good cultivation. The site is dug deeply in winter, manure

incorporated and left rough until February when it is broken down to a fine tilth and firmed well. Seed can be sown $\frac{1}{2}$ in deep in drills during August and planted in March for exhibition onions but the usual practice is to sow seed in late February outdoors or under glass in January and transplant during April in rows 12 in apart with 6 in between the onions taking care to keep the bases about $\frac{1}{2}$ in below the surface. If sown outdoors and thinned the thinnings may be used in salads. Autumn sown onions are liable to bolt but less liable to attack by onion fly than spring sown plants.

Dressings of a balanced feed can be applied but not after July and in August the tops are bent over to hasten ripening. The chief pest is onion fly the larvae of which eat the roots of the seedlings. Control can be maintained by sprinkling the seed drills with Murphy's Gamma BHC Dust or applying a 4 in band of the dust along the rows at the loop stage.

In small gardens onion sets are popular. These are small onions grown in the previous summer sored and replanted the next spring. Plant the bulbs 6 in apart leaving only the necks exposed.

Varieties spring sowing—Bedfordshire Champion Best of All, and White Silverskin (pickling) autumn sowing—Giant Zittau Sutton's Solidity and White Lisbon (salad onions) sets—Ebenezer and Stuttgarter Reisen.

Parsley—Sow thinly in rows 8 in apart during March and again in July for a succession of young foliage thin to 4 in between plants.

Parsnip—Grow parsnips on ground manured for a previous crop, if given fresh manure splitting and forked roots occur. Dig the soil deeply and at sowing time in March work the soil to a fine tilth. On a soil unsuitable for deep-rooted crops special holes 10-12 in apart filled with lifted soil may be prepared. If this method has to be used four or five seeds are sown per hole normally drills 15 in apart and 1 in deep are made and four or five seeds sown every 9 in. The seedlings are thinned leaving one at each station. Parsnips should be left in the ground until needed. Litter over the rows will ease lifting in frosty weather.

Varieties Evesham and Student.

Peas—Dig the ground well in autumn and add a generous amount of manure or compost. Seed sowing begins at the end of February and can be continued at three weekly intervals until early July. Under cloches sowings in January and October will lengthen the season. Both early and late sowings should be of a quick maturing variety. Seed is sown in drills 6-8 in wide and 3 in deep with 2 ft between drills. The seeds can be scattered thinly in the drill or spaced 3 in apart in a treble row. Cover with 2 or 3 in of soil and as soon as the peas are about 2 in high stake with twigs.

Fallures are often due to attacks by birds and field mice. The former should be discouraged by netting and the latter by trapping. Pea sticks will be necessary for the taller varieties which should have 3-4 ft between the rows. With limited space only the dwarf quick maturing varieties should be used. A summer mulch will keep the soil moist and picking should be done regularly.

Varieties 1½-2 ft—Kelvedon Wonder Kelvedon Triumph and Meteor (cloches) 2½ ft—Onward 3½-4 ft—Gladstone.

Potatoes—In general, it is only economic for the amateur to produce an early crop. The main winter supply can be grown if room and labour are available. They should be grown on land well manured the previous season, dressed at planting time with a mixed fertiliser such as National Growmore at a rate of 1½ lb to a 30 yd row. The soil should not contain too much lime, as the damage of scab disease is increased.

Seed tubers about the size of a large egg are best used and these can be bought or saved from the previous season's crop. Large potatoes may

be cut leaving about three eyes to each part. New stocks should be bought occasionally if the seed is home saved to obviate risk of virus. Seed should be put in trays during February in a frost proof shed to sprout and in early April the first earlies can be planted.

Drills 2 ft apart and 4-5 in deep are taken out and the sprouting seed planted 12 in apart in the rows. Maincrop varieties are planted in early May 15 in apart. The young growths should be protected from frost by earthing up slightly and a further earthing is done as the potatoes mature. This practice of earthing prevents the tubers near the surface from becoming green when exposed to light. It keeps weeds down and protects the tubers from spores of potato blight which are washed into the gullies. If growth is poor sulphate of ammonia can be applied at a rate of 1 lb per 30 yd row. Early varieties should mature in late July and later varieties in September and October when the tops (haulm) turn yellow the crop can be lifted, dried for a few hours (too much light will turn them green) and stored in boxes in a frost proof shed or clamps.

SEED POTATOES—Good seed is essential for first-rate crops. Illustration shows (left) a well-sprouted tuber (centre) a large well-sprouted tuber suitable for cutting and (right) a poor, badly sprouted tuber.

Potato blight is a common disease and control by a spraying with maneb before the leaves touch in the rows is effective. Virus diseases spread by greenfly are checked by using "seed" from Scotland where greenfly is less troublesome because of the lower temperatures. Colorado beetle should be watched for and if found notified to the Ministry of Agriculture.

Varieties Discerning growers will find the following well worth growing. Edzell Blue (violet coloured skin excellent cooker) Pentland Dell (white fleshed heavy cropper) Red Craigs Royal (red fleshed heavy cropper) Ulster Chieftain (white fleshed good early variety) Epicureans seeking a first class potato should grow Maris Peer a sort understandably gaining in popularity in Scotland since its introduction. Another interesting sort is the Dutch raised Record a yellow fleshed variety which has a trace of sweetness in its flavour.

Pumpkin—See Melon.

Radish—Although of the easiest culture it is not grown as much as it should be due probably to the damage done by maggots of the cabbage root fly. This pest can be controlled by dusting the seed drills with Murphy's Gamma BHC Dust. Successional sowing can be made in the spring and again in early autumn if desired. Summer sown radish bolt and are hot and tough.

Varieties French Breakfast (cylindrical) and Scarlet Globe (round).

Rhubarb—Before planting the ground should be generously manured and deeply dug. Crowns are planted in March 3-4 ft apart each way and mulched, but no rhubarb should be pulled until the following year when a light pull can be taken. Remove any flowering shoots and give a dressing of sulphate of ammonia if growth is weak. Manure well each winter if early supplies are needed some of the crowns can be covered with inverted boxes or barrels and a packing of loose straw or bracken. An established well cultivated bed will continue almost indefinitely.

Sage—A hardy shrub for the herb garden easily raised from cuttings. The leaves are harvested and dried in summer.

Salsify (Oyster Plant)—A winter root rather like a pansy which requires similar growing conditions.

Savoy—See Cabbage

Scorzonera—A winter root cultivated in the same way as salsify. It has a purplish root instead of the yellow green one of salsify.

Sea kale—A perennial plant native to our sea shores which can be either grown from seed sown in March and left for two years to produce forcing crowns or from bought thongs which are planted during March 9 in apart in groups of three leaving 3 ft between groups. During summer a manure mulch and nitrogenous fertiliser can be applied. When the tops die down in autumn the crowns are covered with boxes to force and blanch the new growths. Crowns can be covered in succession to keep a supply. Earlier sea kale can be obtained by lifting crowns in November. These are planted in batches five or six to a pot watered well, and a second pot with the hole blocked placed over them. In a warm green house or similar position they should develop sufficiently for cutting in about three weeks. Slugs are the chief pest outside and should be kept in check by a proprietary slug killer.

Shallots—A popular crop for the small garden. Shallots are purchased as bulbs like small onions. A deep well manured soil is required as for onions and they are planted during February. The bulbs being pressed about half their length into soft soil, 6 in apart in the rows leaving 1 ft between rows. In mid July the little bunches of bulbs can be lifted. Leave them on the surface to dry for a few days and then store in a dry frost proof shed. Some about the size of a shallot should be kept for planting the following year.

Spinach—Sowings in February to April on a well manured soil will provide a succession during the summer. Sow in drills 1 in deep and 12 in apart and thin the young plants to 3 in and then to 6 in using the second thinning to eat.

When green vegetables are expensive in winter the perpetual or prickly spinach is particularly valuable. Sow in August and treat as for the summer variety.

If plants are crowded or suffer from dryness mildew can be troublesome. Therefore thin seedlings early and water whenever necessary. On poor soils, moisture can be conserved by mulching the rows with peat. Should growth be slow feed with liquid Maxicrop and repeat if required.

Varieties: *America* and *Giant Prickly*.

Sprouting Broccoli—See Cauliflower

Sugar Beet—See Beetroot

Swede—See Turnip

Sweet Corn (Maize)—Gardeners should distinguish between the types of maize used for poultry food and those which supply sweet corn for human consumption. It is wise to use cobs for growing sweet corn as it is only half hardy and resents transplanting. Seeds sown under cloches in mid April in two drills 12 in apart and 1½ in deep should be placed 1 ft apart in staggered positions in the rows. More robust varieties may need 15 in from plant to plant. A soil well manured for the previous crop is best used and a mulch can be given as soon as the plants are a few inches high. The first cobs should be ready by mid July and should be eaten when the cob is milky.

Variety recommended: *John Innes Hybrid*.

Tomato—A sunny sheltered site is required otherwise ripening outdoors in our climate is uncertain. Sow seeds under glass in late March and

harden off the plants in a cold frame or buy plants for setting out in late May or early June. The soil should be thoroughly dug and some artificial manure applied before planting. Allow 15 in between plants and 2½ ft between rows and put in a strong stake with each plant. Keep to a single stem pinching out side shoots regularly. When four or five trusses are set pinch out the top of the main shoot.

Feed with a liquid manure during summer. Fruit which fails to ripen outdoors can be gathered and stored at about 50° Fahrenheit or the plants laid flat on the ground and covered with cloches. When the tomatoes should ripen. Under cloches plants can be planted out in mid April instead of late May gaining six weeks growing time and the cloches removed when they become too large.

Potato blight attacks tomatoes and a spray of maneb during the first week in August and repeated after fourteen days will give a control.

Varieties: *Market King* and *Money maker* some heavy cropping sorts have little or no flavour and a thick skin.

Turnips—Ground manured the previous season should be dug well and dressed with 2 oz super phosphate per square yard. A good early variety can be sown during April in drills ½ in deep and 15 in apart followed by successional sowings at three week intervals as required. The main crop for storage is sown in July and August and seedlings should be thinned gradually to 10 in apart. Use when about the size of tennis balls. A sowing can be made in September left almost unthinned and the tops used as greens in spring. In autumn the storage crop is lifted and all undamaged roots put in sand in a shed or clamped. Flea beetle and turnip fly can be checked by lindane at the seedling stage.

Swedes are grown in a similar manner. Varieties: *turnips*—*Early Milan* (summer) and *Green Top Stone* (winter storage) and *swedes*—*Purple Top*.

FERTILISERS AND ORGANIC MANURES

The elements essential for healthy plant growth may be roughly grouped into classes—first those required in some quantity the major elements nitrogen, potassium, and phosphorus secondly calcium, magnesium, and sulphur which are required in lesser quantities and thirdly the trace elements boron, manganese iron, zinc, copper, and molybdenum of which only minute quantities are needed. As well as the elements mentioned others such as silicon, aluminium, chlorine, nickel, and sodium, are often found on plant analysis but the evidence that these are essential is inconclusive though they may be beneficial to certain crops.

It is important to remember when adding fertilisers to the soil, that different crops may require relatively more of one element than another but a balance between all the elements is essential. As an instance brassicas (the cabbage family) are gross nitrogen feeders while root crops (e.g. carrots) require far less nitrogen and an excess may be harmful. A further point to notice is that although an element may be present in the soil the plant may be unable to absorb any because it is being kept in an insoluble state by excess of another element. An instance of this is the frequent yellow and sickly appearance of plants on very chalky soils due to lack of iron, which is present but locked in an insoluble state by too much calcium.

The elements needed by the plant are in the form of various compounds such as nitrates and phosphates, and may be applied as artificial fertilisers, which are manufactured, or as humus which contains most of the foods required and

also provides the essential soil micro-organisms or bacteria without which the soil would be inert and no plants would grow. Bacteria break down the complicated animal and vegetable matter of which humus is composed to soluble compounds which plants can absorb. Humus can be supplied as farmyard and poultry manure, leaf mould, compost, sewage sludge, spent hops and from animal by-products like hoof and horn, dried blood, meat and bone meal, and many others.

Nitrogen is mainly concerned with vegetative growth, encouraging leaf and stem formation. It is also contained in chlorophyll, the green colouring matter of the plant, and one of the symptoms of nitrogen starvation is a pale green colour to the leaf, indicating a lack of chlorophyll. Most of the nitrogen compounds used are soluble, and it is a wise maxim to apply little and often. If given in large doses much is washed through the soil and wasted.

Nitrogenous fertiliser should not be given to any plant late in the season, as sappy growth easily damaged by winter cold and frosts is encouraged. Similarly, at no time should large quantities be given to any plant, as this results in an excess of leafy growth, which is very susceptible to disease and adverse conditions of drought and cold. Also plants tend to be later flowering.

Sulphate of ammonia is the most used inorganic nitrogenous fertiliser and is excellent for spring use on seed beds, lawns and early crops and it is contained in most fertiliser mixtures. It makes soils acid in reaction and if both lime and nitrogen are required, nitro-chalk should be used instead. Other nitrogen fertilisers used are potassium nitrate, which has the advantage of supplying two major elements at once and is very soluble, and nitrate of soda, often used on beet and mangolds. The latter chemical should not be applied in excess, as too much sodium has a bad effect on soil structure. These inorganic fertilisers are all soluble and quick acting.

As a general guide, 1 oz. of the fertiliser to a gallon of water, applied at 1 oz. per sq. yd. is a good summer dressing given at intervals of two or three weeks. It should always be given after rain or watering and should be applied to the soil and not to the foliage.

Among organic fertilisers containing a percentage of easily available nitrogen are dried blood, soot and meat and fish meals. Slower to decompose and so having a more lasting effect, are shoddy (wool waste) and hoof and horn.

Phosphorus is concerned in the plant with the production of young cells of the root and shoot and also encourages flower and fruit production and early ripening. Most of the compounds are relatively insoluble (rendering absorption by the plant difficult) and so large amounts can be supplied without deleterious effects, especially on acid soils, where the availability is less than on alkaline soils.

Phosphorus is generally applied to the soil in the form of phosphates and among these superphosphate of lime is quick acting and is usually applied at 2-3 oz. per sq. yd. in spring and summer when the need is greatest. More slow acting is basic slag, a by-product of the steel industry sold as a fine black powder and containing besides phosphates many of the trace elements, as well as a considerable percentage of lime. This is good for application to acid, wet soils, but should not be applied to potatoes owing to the risk of scab disease with the increase in the content of lime. It should not be applied with sulphate of ammonia. Bonemeal is also slow acting and also contains some nitrogen. It is excellent for crops like tomatoes, and is also used extensively for ornamental and pot plants.

Potassium, the third major element, is essential for good flower colour and ripeness in fruits. Dessert apples, potatoes, cereals and root crops all need potash in some quantity and if excess nitrogen has been applied a dressing of potash may counterbalance the effect. Sulphate of potash is the main inorganic compound in use. Muriate of potash (potassium chloride) to which some crops are sensitive is much less used. It should be

applied as a winter dressing before the crop is sown to lose the impurities by weathering. Sulphate of potash is purer and may be applied during the growing season at 1 oz. per sq. yd. on the vegetable plot and is used in many proprietary fertiliser mixtures.

Wood ash contains variable quantities of potassium, and provided that the ash has not been washed by rain and the potassium leached out, is a useful addition to the soil, bracken cut during June and July when large amounts of potassium are present in the foliage, can be composted when green to provide a good supply of the element.

Elements Required in Lesser Quantity—Calcium, although required in small quantities in the plant, has profound effects on the soil. Its main function in the plant is in the production of the cell walls, but in the soil it helps to bind light soils together and to make the structure of sticky clay soils finer and more workable. Also soils without calcium are acid and tend to lock up some elements in an insoluble form. Addition of calcium changes the acidity, making it slightly alkaline or neutral and releases the locked elements.

Calcium is applied as some form or derivative of calcium carbonate, commonly known as lime, which can be obtained in various forms. Hydrated or slaked lime (calcium hydroxide) is commonly used on clay soils and chalk or ground limestone on lighter soils. Calcium is gradually leached from the soil and it is necessary to replace it or the soil becomes too acid and many crops will fail to grow. A normal dressing of lime for a vegetable garden is about 4 oz. lime or 1 lb. chalk per square yard every two or three years and is best applied in autumn as a surface dressing after digging. It should not be applied together with other fertilisers. The amount of lime will depend on the type of soil, but it must be remembered that most vegetables grow best on a slightly acid soil.

Gypsum or calcium sulphate, is sometimes recommended to supply calcium, but its solubility is negligible and it is preferable to chalk or limestone only on soils containing salt due to sea flooding. It was used to help reclaim districts of East Anglia flooded by sea water during the storm surge of January 1953 by improving the soil structure. Sulphur, as sulphates and magnesium, as an impurity in limestone, are usually present in sufficient quantities for the plants needs.

Trace Elements—In the case of the trace elements, most soils contain enough for the plant, but in certain circumstances deficiencies occur. Iron on very alkaline soils is insoluble and as it is essential for the production of chlorophyll, deficiency results in the chlorosis of the leaves. It can be rectified by spraying the leaves with Sequestrene. Likewise the lack of magnesium and manganese can be remedied where deficient on acidic soils.

Chlorosis in brassicas can be due to a deficiency of both manganese and magnesium. Boron deficiency often occurring on light, calcareous soils is responsible for brown heart of cauliflower and several other diseases, mainly affecting the growing point. It can be rectified by applying borax to the soil at about 1 oz. per 15 sq. yd. Zinc and copper deficiencies are unusual in England but lack of molybdenum has caused whiptail disease of cauliflower. Only minute quantities of the last three are required, more may be poisonous to plants and animals.

Organic Manures—It should be noted that most of the deficiencies will not concern the amateur, especially if he keeps the ground in good heart with ample organic manure, which contains all the plant foods necessary. Well rotted farmyard manure from cows and pigs is by far the best organic food, but is scarce now, good farmers returning it to their own land, and generally the material offered is low in nutrients. Poultry manure, which is rich in soluble nitrogen salts, is excellent either applied direct to the soil (not to the growing crop for fear of damage) or composted with straw.

Many substitutes have been devised to use in place of manure among them sewage sludge best applied some time before growing the crop spent hops from breweries dried seaweed excellent for potatoes when supplemented by superphosphate soot rich in nitrogen composted town refuse and the waste organic animal products mentioned earlier. The organic matter in all these materials is essential for maintaining the soil structure and cannot be replaced simply by artificial fertilisers.

Liquid manure produced by suspending an old sack of animal manure or soot in water for a few days is useful for the amateur to apply to pot plants and to individual crops like sweet peas tomatoes and chrysanthemums. Leaf mould and peat can be used as a mulch and also to supply organic matter to the soil. Sawdust in a well rotted condition is also useful for inclusion in compost and as a mulch. It is emphasised that it must be well rotted and it is advisable to apply a nitrogen fertiliser such as sulphate of ammonia at the same time.

Of the proprietary organic manures the seaweed one called Maxicrop has given good results when used on vegetables and flowers.

Compost making—The methods developed for making compost heaps are many and various they depend on three basic principles good aeration, plenty of moisture and a nitrogen supply for the decomposition bacteria. A fairly simple method by which much garden and house refuse can be utilised is as follows. An area about 9 ft by 4 ft is marked out and all waste vegetable matter—weeds lawn mowings cabbage leaves pea haulm, straw dead leaves and hedge clippings—are put in this area and trodden down. Care should be taken not to use diseased material but grass clippings and weeds which have been recently treated with hormone weed killers may be applied. When the heap is about 9 in thick it is sprinkled with sulphate of ammonia and superphosphate at $\frac{1}{2}$ oz of each per square yard (2 oz of each for a 9 ft by 4 ft plot) and any wood ash available and then sprinkled with 4 gallons of water and covered with an inch of soil. This process is repeated with 9 in layers of rubbish until the heap is about 4 ft high when it is better to begin a second heap. A sprinkling of ground lime may be given as each layer is added but should not be applied until after watering to avoid reaction with the sulphate of ammonia.

The completed heap should be watered occasionally and after about a month or six weeks if time permits it can be turned completely over watered again and re covered with soil. The heap may then be left until rotted and the compost can be dug in as required. Any unrotted material can be used as a basis for a new heap. The time taken for rotting will vary with the time of year and material used but generally a compost heap made during the summer should be available for autumn use and one made during the autumn ready for spring use.

There are a number of compounds on the market known as compost makers which are said to accelerate the decomposition but in general a heap made in the way described is eminently satisfactory and although requiring a certain amount of labour is the least expensive way of obtaining humus for the garden. This latter point is extremely important nowadays with the scarcity of animal manure and the high costs of both inorganic and organic fertilisers. Prices are of course not static but comparatively the organic manures, such as dried blood, hoof and horn, and guano are more expensive than the inorganic salts, but these lack humus, which is an essential of a well cultivated soil.

General Fertiliser—Many firms supply compound fertilisers containing given amounts of the main nutrients needed in either liquid or powder form, and some are made up with quantities of nitrogen, potassium, and phosphorus suitable for specific crops like roses, tomatoes and chrysanthemums. A general fertiliser which can be made up by the amateur is as follows:

- 7 parts by weight superphosphate.
- 5 parts by weight sulphate of ammonia.
- 2 parts by weight sulphate of potash.

Encouraging results have been found with Maxicrop, a seaweed manure used as a general feed. In bulk purchase it returns good value for money.

Green Manuring—Another method of enriching the soil with organic matter is green manuring which has been practised for some time by farmers and can no doubt be adapted to the gardener's purpose. Green manuring consists of planting a fast growing catch crop and ploughing the mature crop back into the soil. Legumes are especially good for this as certain bacteria in their roots can fix the nitrogen in the air. Field peas sown at 4–5 oz per sq yd and Italian rye grass at 2 oz per sq yd are commonly used while clover and annual lupins are also suitable.

If sown after an early crop on land needing organic matter the green manure may be dug in during late summer. Alternatively if the land is not being cropped at all during the year two green manure crops may be grown, an early sowing of field peas in April may be dug in during July and a further sowing of field peas or Italian rye grass sown immediately after may be dug in following the first few frosts.

New chemicals often appear on the market at exorbitant prices and with fantastic claims as to their value as soil conditioners and the like. Contrary to this generalisation, in recent years a chemical known as Gibberellin has been used to increase the growth of certain plants. It is now available to the amateur but should be used with care and mainly in the spirit of experimentation as no conclusive proof of its efficacy has yet been put forward.

GARDEN PESTS

Every garden abounds in insects and other small creatures but comparatively few species are pests which feed on plants. The great majority are quite harmless while many are positively beneficial and help to keep the number of pests under control by catching and eating them. Every good gardener should make it his business to be able to differentiate between friend and foe. This is not always easy but the speed of a creature's movements may often provide a clue. Fast running active creatures such as the black ground beetle or the centipede are usually beneficial, while the slow moving and sluggish ones, e.g. wireworms, aphids and caterpillars are usually pests. This is by no means an infallible rule but it is handy to remember when in doubt.

The good gardener should also get to know the pests which are most prevalent in his district and which can be expected to crop up year after year. The first principle of good control measures is to act while an infestation is still in its early stages and before a great deal of damage is done. When one knows what to expect steps can be taken to prevent an attack or to stop it developing to serious proportions.

Also from the experience of past years one can often forecast whether a pest is likely to be as numerous enough to make chemical treatment worthwhile. Remember insecticides can become an expensive item and there is little point in using them if the damage is negligible. In these circumstances insecticides may eventually increase the numbers of pests since the treatment will also have killed off many of their natural enemies which had hitherto kept the pests under adequate control. In addition good cultivation and general garden hygiene helps to reduce the numbers of pests.

The common pests of garden plants can be roughly divided into four main groups.

I. Root Pests.—These destroy the feeding mechanism of plants or tunnel into fleshy tap roots, tubers and bulbs. Attacked plants make poor growth and may eventually wilt and die.

Some insects are general root feeders. These include (a) Swift Moth Caterpillars, soft white caterpillars with reddish brown heads. (b) Chafer Grubs, large C shaped whitish grubs with chestnut brown heads. (c) Wireworms, long cylindrical, yellowish brown grubs with a hard shiny skin and (d) Leatherjackets, greyish black grubs with a wrinkled leathery skin. These are particularly prevalent in recently cultivated grassland or in gardens surrounded by fields, and will attack the roots of a wide range of plants. Chafer grubs however are particularly fond of the roots of shrubs and wireworms will often tunnel in potato tubers and other fleshy roots whereas leatherjackets prefer the roots of grasses and may cause browning on large patches of lawn.

Badly infested ground should be dressed with lindane dust when cultivating, working the dust into the top 4 in. of soil. Where this is not possible i.e. on lawns or around established shrubs the liquid form of the insecticide should be watered into the soil.

Cutworms are stout fleshy caterpillars varying in colour from greyish brown to dingy green. They feed on roots during the day but at night come to the surface and feed at the base of the stems of plants causing them suddenly to collapse and wither. Brassicas and lettuce are commonly damaged in this way and the pests should be removed by hand and killed when the soil is cultivated.

Millipedes are hard skinned cylindrical creatures brown or black, with numerous short hairs like legs. They are slow moving and curl up when disturbed and should not be confused with the active long legged centipedes which are beneficial. Millipedes commonly extend the damage made by other pests, such as slugs and wireworms. They also bore into the sown seeds of peas and beans. During the day they hide in dark, damp places such as long vegetation or under stones and pieces of wood. Such hiding places should be removed or dusted with lindane. Drills for peas and bean seed should also be dusted before covering.

Weevil Grubs, small, curved white grubs, may infest the roots of pot plants and plants in rockeries. Such plants should be removed, the roots cleaned, and replanted in soil which has been dressed or mixed with lindane dust. Where it is not practicable to remove the plants they should be watered copiously with a liquid form of these insecticides and soil dressed properly at the earliest opportunity.

Slugs need no description. They vary greatly in colour. The most destructive are the under ground keeled slugs, small, grey black in colour which tunnel in roots, tubers, and bulbs. There are also several foliage-feeding species which rasp holes in the top parts of plants. Slugs like wet conditions and much can be done to control them by ensuring that the soil is well drained and that long tangled vegetation is removed.

Poison baits can be bought or made by mixing 1 oz metaldehyde with 3 lb bran (or bonemeal for keeled slugs). The bait is sprinkled over the infested ground or distributed in small heaps and protected from the rain. There is also available on the market a metaldehyde spray for dealing with the foliage-feeding types.

Cabbage Root Fly attacks brassicas and wall flowers. The small white maggot eats away the side roots and tunnels in the main root causing the plant to wilt and collapse. The roots of young seedlings should be dipped in lindane before planting out. Alternatively the plants can be given a drench of lindane within four days of planting out.

The maggots also tunnel in radishes and turnips, and this can be avoided by dusting the seed drills with lindane.

Carrot Fly—The maggot of this fly tunnels in carrots and parsnips. Where the pest is serious it is best to delay sowing until the end of May. If possible seeds should be sown in exposed,

windy places which are avoided by the egg laying flies. Seedlings should be dusted or sprayed when 2-4 in. high with Murphy's Lindax Garden Spray an approved chemical.

Onion Fly maggots tunnel into the bulbs of onions leeks and shallots causing the foliage to collapse. Dig out attacked plants carefully ensuring that parts of them are not left in the soil and burn them. To prevent attacks dust around the seedlings with lindane when they are at the loop stage i.e. about 1 in. high and again ten days later.

Narcissus Bulb Flies are serious pests of narcissi and also snowdrops and other bulbous plants. The maggots burrow in the centre of the bulbs causing them to rot. All soft bulbs should be burned and the remainder immersed for three hours in a solution of lindane containing a wetter. To prevent future attacks and a reinfestation dust around the necks of growing bulbs with lindane at fortnightly intervals from the end of April until the end of June.

Insects which feed above ground include

II Sucking Pests pierce the tissues of plants with needle like mouth parts and suck the sap. This debilitates the plant checks growth and causes wilting. Some species cause distortion of leaves and young shoots and aphids suckers scale insects and mealy bugs excrete a sugary fluid which disfigures the foliage attracts ants and allows the growth of sooty moulds.

Aphids, i.e. blackfly greenfly etc are serious pests which attack almost all plants and multiply rapidly in warm weather. They feed on the shoots and undersides of the leaves, and many species are responsible for the transmission of virus diseases. Infestations should be treated as early as possible. Malathion and nicotine both give excellent results if used properly and thoroughly to both the surface and undersides of the affected foliage. With the advent of these sprays the control of aphids on roses and broad beans for example is no longer a serious problem.

Tree fruits should be sprayed when the buds are bursting and again when the flower buds are still green. Currants should be treated at the grape stage but lindane should not be used on this fruit. Tar oil applied to deciduous woody plants while they are completely dormant will kill the overwintering stages of these and many other pests. It does not however give a good winter control for Woolly Aphis on apples. This pest is best controlled by spraying at the pink bud stage with B.H.C. with a succinate spreader added. Small colonies on the bark can be eradicated by painting with 10% tar oil.

Some aphids feed underground on roots particularly of lettuces, currants and cacti. Where practicable infested plants should be lifted and the roots cleaned and sprayed before replanting in clean soil. Otherwise water them copiously with malathion or lindane.

Scale Insects are often found in greenhouses but also occur out-of-doors on trees and shrubs. Flat or dome-shaped, these creatures spend most of their lives immobile, and they do not at all resemble insects, or even appear to be alive. Again tar oil is useful for killing the overwintering stages on deciduous woody shrubs which are dormant. Plants which are in leaf should be sprayed with malathion or nicotine/white oil emulsion two or three times at fortnightly intervals. These substances are more effective if as much as possible of the scale is first removed by means of a sponge, brush, or scraper with water in which soft soap has been dissolved. Mealy Bugs are common pests of greenhouse plants, and should be given the same treatment as scale insects.

Capsid Bugs are very active insects which cause considerable damage to fruit trees and bushes and also to various ornamental plants principally

chrysanthemums and dahlias. They feed on the young leaves, causing distortion and raggedness, and on the buds, which later produce misshapen blooms. These in sets green or reddish in colour can be controlled by spraying with lindane when the flower buds are still green as for instance on fruit trees. Herbaceous plants should be sprayed twice or three times at three weekly intervals starting when the plants are young and before the damage is seen. Less persistent insecticides which can be used in this case are malathion and nicotine.

Leafhoppers are small, yellowish green insects like aphids but much more active. They feed on the undersides of the leaves of a variety of plants causing them to become speckled with yellow. Roses are commonly attacked. The treatment given to capsids on herbaceous plants will control these also. The sprays being directed to the undersides of the leaves.

Whiteflies are serious pests in greenhouses and also occur out of doors on rhododendrons and other evergreen shrubs. The adults are like miniature moths with white wings and the young are small scale like creatures generally greenish in colour which feed without movement on the undersides of the leaves. To control all whiteflies lindane or malathion should be used as a spray or smoke two to three applications being given at fortnightly intervals.

Red Spider Mites are extremely small creatures red or greenish in colour and just visible with the naked eye. They feed on the undersides of the leaves of many greenhouse and outdoor plants including fruit causing the leaves to turn sickly yellow. Control is difficult. The most effective materials being malathion, derris, summer oil, or azobenzene smoke. The directions on the labels of these products should be followed carefully.

III Biting Insects have chewing and biting mouth parts which are used to cut away pieces of plants.

Caterpillars (the young stages of moths and butterflies) are the best known pests in this group. They vary in size and colour according to the species and most plants are liable to be attacked. These should be sprayed or dusted with derris as soon as the damage is noticed.

On apple and pear trees caterpillars can cause serious trouble and in this case treatment should take the form of a pie blossom spray with tri chlorphon.

The greatest problem with caterpillars arises with the well known large and small white butterfly which in some seasons skeletonise the leaves. The worst damage is in the late summer when the infestation has built up to its highest point. Control is laborious: crush the egg clusters of the large butterfly and remove colonies of caterpillars by hand. As far as chemical control is concerned this should be restricted to the use of derris up to within two weeks of picking. In recent years various other chemical controls have been suggested and applied on a large scale but their use is not now recommended unless specific approval has been granted. See T31.

Sawfly Caterpillars are very similar to those above and commonly attack gooseberry and rose foliage. They can be controlled by spraying with malathion or derris.

Attacks by the Apple Sawfly which burrows in young apples and forms ribbon like scars on the skin can be prevented by spraying with lindane seven days after 80% of the blossom has fallen.

Beetles and Weevils which feed on foliage are usually best controlled by spraying or dusting with derris. To kill the tiny Flea beetles which eat small holes in the seedlings of brassicas and turnips treat the plants at fourteen day intervals until they reach the rough leaf stage.

The golden brown Raspberry Beetle, which feeds on the flowers and whose grub tunnels in the fruit is best eradicated with derris applied ten days after full bloom and again ten days later. For other common pests in this group *eg* Vine

Weevil Clay coloured Weevil Pea and Bean Weevil etc apply the derris as soon as the damage is first seen.

Earwigs feed at night on the foliage and flower petals of many plants. They bite by day inside flowers in the folds of leaves and in nooks and crannies on the ground under flat stones etc. These pests are killed by derris applied to the plants (but not to open flowers) and to their hiding places.

Leaf Miners are very small grubs which tunnel between the upper and lower surfaces of leaves forming pale blisters as on lilac, holly, celery etc. or long twisting galleries as on chrysanthemum, pea and tomato. In small infestations the affected leaves should be picked off and burned. Otherwise spray with lindane as soon as the damage starts giving three applications at fourteen day intervals.

IV Eelworms are microscopic pests which are invisible to the naked eye. They are able to live for very long periods without food and are extremely difficult to eradicate. The most common species are

Stem and Bulb Eelworm which infests narcissus, phlox, strawberry, hyacinth, onion and other plants. Infested plants show distorted foliage and dwarfing and gradually deteriorate. They can only be sterilised by immersion in hot water kept at well defined temperatures for one to three hours but expert diagnosis and advice should be obtained before this or any other control is attempted. Infested ground must be kept clear of any host plants for at least three years to starve out the eelworms.

Chrysanthemum Eelworm causes the formation of yellowish blotches between the veins of chrysanthemum leaves which later turn black and drop off. In severe infestations the blooms are undersized and malformed. Expert advice should be obtained before control measures are attempted.

Potato Root Eelworm is a serious and widespread pest of potatoes causing the plants to become stunted and sickly giving very poor yields. The pest can only be kept in check by crop rotation potatoes being grown on the same ground only once in four years. This is difficult in small gardens and where land becomes heavily infested the only remedy is to rest it from potatoes for at least five years.

The Purchase and Use of Insecticides—To ensure that an insecticide will do what the maker claims it is advisable only to buy brands which have been tested and approved by the Ministry of Agriculture. This can be ascertained from the Approval Mark (T31) on the label. Read the directions and following them carefully. Never apply insecticides to flowers in bloom otherwise many valuable pollinating insects will be killed.

DISEASES OF PLANTS

Plant diseases are important because they can cause great loss not only in growing crops but also in the produce after it has been harvested and stored. The skill in growing crops is wasted if they are destroyed by disease and many people know the wastage of potatoes through blight disease in winter stores and rotting of onions when they decay through neck rot disease. For these reasons the keen gardener must take notice of

diseases and use the knowledge available to him in checking them wherever possible.

The most important point to remember about plant diseases is to recognise the first signs so that the remedy can be applied at once. In greenhouses this is of great importance because the atmosphere is warm and moist and in such conditions diseases flourish. It must also be remembered that the same crop is often grown in the same soil in a greenhouse so that we get a build up of disease and this causes the well known soil sickness. This means that new soil must be brought in or the old soil enriched and also sterilised by steam or by chemicals. Even frames and propagating pits require periodic cleaning up by a disinfection treatment.

Unlike insect pests the actual cause of a plant disease cannot be seen with the naked eye and microscopic examination is required for its detection. The scientists who study diseases are called plant pathologists and these are stationed

on other healthy plants where they germinate and spread the disease. This occurs in the growing season but when winter approaches the parasite forms tough resting bodies of one kind or another and these are resistant to extreme cold.

They overwinter in the soil or in the surface of tree bark etc. so that in the following spring they can germinate and cause disease again. So we get the reappearance of such troubles as damping off in seedlings, scab in apples, brown rot in apples and plums, foot rot in peas, wart disease in potatoes, mildews on all kinds of plants and so on. This question of soil contamination by overwintering spores is one of the most serious in the fight against plant disease.

The signs of fungus and bacterial diseases are varied and may show as yellowing, silvery brown spotting or blackening of leaves (potato blight, rose black spot, celery leaf spot, antrachnose, rust) as stunting (cabbage wire stem) as pustules and cankers in stems (coral spot, apple canker) as gumming or dieback in branches (rose canker, plum dieback) as galls, warts, witches brooms or other malformation (club root in cabbages, crown gall, leafy gall, peach leaf curl) as dry or soft rots of fruits, tubers, vegetable bulbs, and corms (gladiolus dry rot, potato dry rot, iris rhizome rot, celery heart rot) and many other abnormal conditions. Sometimes only a part of the plant is affected and can be removed, e.g. branches showing attack by coral spot or one of the large bracket fungi seen on trees, these having gained entrance through a wound.

2 Virus Diseases.—This class of disease is becoming increasingly important as more is discovered about them, although research on them is a comparatively recent development. A virus disease is caused by infection with a virus and the exact nature of this is not yet clearly understood, but it is so small that it cannot be seen with ordinary microscopes. Its detection is therefore not easy but when the sap of a virus diseased plant is injected into a healthy one it causes the disease.

In nature this spread is brought about by biting and sucking insects which are referred to as **Vectors**. They transmit the virus by feeding on infected plants and then travelling to healthy ones, on which they feed and so spread the disease. Most viruses are transmitted by aphids (greenflies).

In the garden and nursery they can be carried from plant to plant by pruning knives or by the fingers in the process of trimming plants such as tomatoes, melons and cucumbers or by the use of the knife in taking cuttings. In general the virus does not kill a plant quickly but tends to cripple it and cause a slow deterioration. Infected plants cannot recover but remain sometimes for years, as sources of infection on which insects feed and carry on the disease. So viruses may increase in lily stocks, strawberry beds, and raspberry plantations unless virus-infected plants are removed and aphids strictly suppressed.

The signs of virus disease are of different kinds, but the commonest are those of the type called **mosaic** in which the leaves show a mottling with light green or yellow patches scattered in irregular fashion on the darker green of the leaf. There may be also some reduction in the leaf blades. These symptoms can be seen in the mosaic of cucumber, vegetable marrow, lettuce, cabbage, turnip, tomato, delphinium, primula, dahlia, apple, raspberry and many other common plants. In some, such as lilies, daffodils and onions the mosaic is more in the form of stripes down the leaf blades.

Another virus symptom is **flower breaking** where the normal colour of the petals is broken by streaks and spots of white, and this can be seen in tulip, wallflower, pansy, stocks or carnations affected by the mosaic virus. Other viruses cause **bronzing** of the top leaves (as in tomato spotted wilt) or small light-coloured rings arranged in concentric circles (as in dahlia ring spot) or even reduction of leaves until they are tendrils like (as in tomato fern leaf). Sometimes there is **malformation** or even proliferation, producing innumerable stunted shoots, as in blackberry dwarf disease.

The important point to note about these virus diseases is that every part of the plant is quickly

THE APPROVAL MARK—An officially approved crop protection product shows on its label this design.

at universities and other institutes throughout the country where they carry out research on various plant troubles and advise on suitable remedies for checking them. It is obviously necessary to understand the exact cause of a disease and how that cause operates before a means of checking the trouble can be devised. The advice can then be passed on to growers, farmers and the gardening public.

The presence of disease in most cases can only be detected by the symptoms shown by the affected plant which is called the **host plant**. The actual cause must then be determined by careful examination in the laboratory which is done by the pathologist.

Plant diseases in general are divided into three classes as follows: 1 Fungus and Bacterial, 2 Virus, 3 Functional Disorders.

1 Fungus and Bacterial Diseases.—The first kind called fungus diseases are caused by the attack of fungus parasites, examples being the well known club root of cabbages, potato scab, apple scab and plum brown rot. These parasitic fungi are microscopic and composed of fine threads but they attack plants and penetrate them either through wounds (insect bites, hail damage, pruning cuts) or directly through the surface cells (epidermis). The threads grow into the plant, killing the cells and absorbing their contents. There is usually some discoloration or even decay of the tissues around the point of infection, but it is possible for the plant to show distress in one part although the parasite is at work some distance away. Examples are silver leaf in plums and the honey fungus which kills trees by attacking the roots.

The fungus spreads by means of spores which are equivalent to seeds in flowering plants but which are microscopic in size. These spores are produced on the surface of the plant in enormous numbers and are blown (wind), splashed (rain), or carried (insects etc.) in all directions to alight

infected, so that the sap is infectious to other plants of the same kind. The virus is present in all parts and for this reason it is useless to propagate from a virus infected plant. This means that all the scales and offshoots from bulbs such as lilies and tulips, all the tubers from potatoes and all cuttings from herbaceous plants which are taken from a virus infected plant are useless because they will carry the virus. They should be destroyed and the only exception is where the plant is greatly valued in which case seed can be taken from it before it is destroyed. In general viruses do not travel in the seed and only in one or two cases is seed infected and this only in negligible quantity.

3 Functional Disorders.—This third class of disease is often called non-parasitic because unlike the previous two kinds there is no parasite involved and these troubles are therefore not infectious. They are due to faulty cultivation or unsuitable environment in which soil conditions or climate affect the plants adversely. In this group we include cases of unsatisfactory growth due to waterlogging, drought, frost, high temperature damage by fumes or atmospheric pollution, or even excess lime.

Perhaps the most important kinds of trouble in this class are the so called Deficiency Diseases where the plants suffer from shortage of some important food. This may be one of the common food substances such as nitrogen, potash or phosphate and details will be found under the section on manures and fertilisers (T26).

CONTROL OF DISEASES

1 Garden Hygiene.—The control of plant diseases can be dealt with only briefly but to begin with we must emphasise the value of good cultivation as an insurance against losses from disease. Robust plants are better able to stand up to disease than sickly ones and everything in the way of proper drainage, soil aeration, proper spacing, sensible feeding and so on will help to keep the plants vigorous and thus is the first line of defence against diseases. Garden hygiene is important; weeds need to be kept down, wounds in trees and shrubs covered with a good paint against infection, new stocks examined carefully, seed bought only from reliable sources, diseased plants burnt and dead material regularly removed from plants especially in greenhouses.

2 Soil Sterilisation.—There are other precautions among which the sterilisation of the soil in greenhouses by means of steam or chemicals is of some importance. Dazomet can be used outside but rotation of crops is a most useful system in helping to avoid disease. Disinfection of frames propagating pits and seed boxes by formalin or cresylic acid are other useful measures.

All these operations aim at destroying the resting spores of fungus parasites responsible for such diseases as tomato leaf mould, gladiolus dry rot, damping off in seedlings, root rots and downy mildews of many kinds in young plants such as stocks, cheiranthus, cineraria, tomato aster and calceolaria when grown in boxes or pots.

3 Disease Resistant Plants.—The use of disease resistant varieties of plants is very desirable but there are not many kinds available and often the resistant kind does not possess flowers or fruit of such fine quality or flavour as the more susceptible kind. The outstanding success of this kind is that of potatoes immune to the dreaded wart disease and these can be grown safely in the most heavily infected land. There are antirrhinum resistant to rust disease and there is resistance in some degree in the case of delphinium mildew, potato blight, tomato leaf mould and some others. Research goes on to discover still more, because any such plants are always worth a trial.

4. Treatment of Seeds and Bulbs.—For seed borne diseases seed treatments may be done with

captan or thiram seed dressings or even by immersion of the infected seed in warm water.

In some diseases for example tulip fire we can protect the bulbs from the danger of infected soil by raking in a powder such as Botrillex when planting the bulbs and a similar treatment is done with calomel dust against club root in beds intended for sowing brassica seeds.

5 Fungicides.—Even after all this a disease may still appear in the crop and more direct action must be taken. It is then necessary to protect the plants by means of a Fungicide. This is a chemical which is poisonous to fungus parasites but which will not harm the crop plant (host). Fungicides are used as wet sprays or in powder form as dusts and they are sprayed or dusted all over the plants to protect them from infection by diseases.

The object of the treatment is to cover the plants with a film of the fungicide so as to protect the still healthy ones. To help the spray fluid to spread over and adhere to the foliage another substance called a wetter, spreader or sticker is added to the spray but sometimes this is already included by the manufacturer.

5 (a) Sprays.—Sprays are applied by means of machines called sprayers which vary from small hand syringe types giving a continuous jet of spray to those pumped up to a pressure and carried on the back (knapsack machines) and so on to the large machines driven by a petrol engine which deliver the spray at a high pressure. It is necessary to have a suitable nozzle giving a fine mist like cone of spray which settles on the foliage and is not wasted.

5 (b) Dusts.—Dusts are similar chemicals produced in such finely divided form that the powder can be blown over and on the foliage almost like a fog. This is best done after a shower of rain or after a heavy dew. The machines used are far more varied in design than spraying machines. There are small hand dusters worked either like a small pump or like a bellows of which the Acme is a good example and there are those which are carried on the back and worked as a double bellows action or on the front of the body with a rotary fan action. It is important in gardens to clean and dry the machines after use and small sprayers may be best put upside down to drain for a time after use.

The substances used as sprays and dusts against plant diseases for many years have been copper and sulphur and their compounds. Perhaps the best known copper containing spray is Bordeaux Mixture which is still a good spray but which has been largely replaced by liquid copper available as Murphy's Liquid Copper Fungicide for such diseases as tomato blight etc. Sulphur is used extensively as lime sulphur against apple scab and as colloidal sulphur against the powdery mildew diseases. As dusts copper is mixed with lime to give copper-lime dust and sulphur is used alone either as flowers of sulphur or green sulphur.

5 (c) The Newer Fungicides.—In recent years much research has been carried out in tests to see whether other chemicals have value as fungicides and the search has been in the field of organic chemistry and among all kinds of these chemicals. Tests of this kind take a long time, but a few substances have already been picked out as showing special promise and we can mention captan which is so good against apple and pear scab, zineb against tomato leaf mould, onion mildew and tulip fire and dinocap against any of the powdery mildews such as American gooseberry mildew, strawberry mildew, vine mildew as well as the same diseases on ornamental roses, delphiniums, michaelmas daisies and other plants.

6 Control of Viruses.—The control of virus diseases is very different, because in this case the only spray treatments likely to be of use are those designed to keep down insects. The other necessary control measure is to remove and destroy the virus-infected plants which are a danger as sources of infection.

This is best done when the plants are young so that any young marrows, cucumbers, dahlias, delphiniums, sweet peas, lupins, lilies, etc., which show virus symptoms, as commonly revealed in leaf mottling and poor growth, should be removed as soon as detected. Propagation should be done carefully so that young stock is not propagated from stocks of strawberries, raspberries, and all kinds of herbaceous perennials which show signs of virus infection. Even the knife used for taking cuttings should be wiped occasionally on a rag dipped in a good disinfectant.

7 Prevention of Functional Disorders.—In the case of Functional Disorders (non parasitic diseases) it is not always easy to advise remedies. Where the soil conditions are faulty attention can be directed to improving drainage if necessary or counteracting dryness by digging in humus, irrigating, and general mulching. Dryness at the roots of tomatoes causes loss of fruit, and so does extreme dryness in the air of the greenhouse but these should be adjusted fairly easily.

Frost damage can spoil many crops, but robust foliage may help a little to lessen the damage. Late frost damage to fruit in some areas can be lessened by various methods of cultivation and planting. The effects of drought can be aggravated by shortage of certain foods, especially potash, so that even here some attempt can be made to avoid loss. Excess liming may cause food shortages by causing the appearance, in the leaves, of a yellowish or even whitish colour, which is known as lime-induced chlorosis. The real reason may be lack of iron or manganese due to the excess lime in the soil, but recently very good results at counteracting this condition have been obtained by using the substance known as Sequestrene.

Another method of treating these food shortages is to spray the young foliage in early summer with the required element in a very weak solution. They can even be included in sprays used for keeping down diseases or pests. It must not be forgotten that even the ordinary foods such as nitrogen, potash, and phosphate may sometimes be in short supply, and the effect can be seen by the trained plant pathologist. In these cases the effect may not always show clearly in the growing crop, but may appear long afterwards in the stored fruits and vegetables, which as a result deteriorate and break down long before they are required for use.

The present-day methods of cultivating large numbers of the same plant in one spot tend to increase the risk of large-scale disease attacks. Modern plants may be highly bred and selected for great purity of strain. Indeed they have often been chosen for fine quality and flavour with little regard to their ability to resist disease, so that the gardener must always be ready to give them the protection they may need.

USES OF MODERN WEEDKILLERS.

The eradication of weeds by chemical means is one of the greatest advances of recent years, albeit the value of herbicides is still unappreciated by most gardeners. With a planned programme all cultivated ground and lawns can be kept free of weeds without hoeing or any other sort of manual cultivation.

Occasionally troubles have arisen in not following makers' instructions. Sometimes the damage has been most unfortunate, as the majority of herbicides are toxic in varying degrees, to a wide range of plant life. In the main, controls are determined by circumstance as typified in the following cases.

Asparagus Beds—Annuals and top growth of perennial weeds can be controlled with cresylic acid in the autumn and before the asparagus appears in the spring. In beds free of perennials a

first class control of weeds can be maintained with Simazine applied in the early spring.

Where annual and perennial grasses predominate, Dalapon or Diquat will give good control. As for bindweed this may be eradicated by watering the foliage with 2-4-D in late July or August, taking care to avoid contact with the asparagus stems and particularly the fern.

Fruit Garden.—Around blackcurrants, gooseberries, raspberries, apples, and pears, grasses can be killed with Dalapon. Once clear of perennial weeds, annuals may be controlled effectively with Simazine. Alternatively, weeds may be killed with Diquat, making applications as necessary throughout the season.

Garden Paths.—On any surfaced path or drive a first rate control of weeds can be maintained by watering with a residual herbicide such as Simazine. As this preparation is virtually insoluble in water, it does not seep through the soil as sodium chlorate would, and therefore it can be used near garden crops and grass edgings. Further to this, it is not easily washed from the soil and remains active near the surface for up to twelve months. Notwithstanding the herbicide must be used with proper care.

A dilute solution of sodium chlorate with 4-6 ozs. to a gallon of water may be applied, but it is liable to affect plants near by and for this reason application should be confined to the centre of the path, thereby leaving room for the chlorate to seep through the soil.

Lawns.—The majority of weeds in turf can be eradicated easily with formulations of 2-4-D or M.C.P.A. (see Finding List). In particular, dandelions, plantains, and most broad-leaved weeds are susceptible, although it may be necessary to repeat the dose after 10 days. The best time to do the work is on a warm fine day in the spring when the plants are growing actively, and there is the prospect of fine weather to follow for twenty-four hours. The action of the herbicides is rapid and grass may be cut after a couple of days, composting with mowings in the normal way. It appears that the hormones are not injurious to bacterial life in the soil and in a few weeks break down into harmless substances.

Where bulbs are naturalised in grass, steps to control weeds should not be taken until the foliage of the bulbs has died down and the bulbs are dormant. Thus as a general rule, control measures are best applied throughout July.

To deal with weeds in turf where there arises the danger of the spray—or even a drift from it—touching cultivated plants near by, as for instance on grass paths in a rose garden, then one of the plastic canes filled with a solution of hormone can be used to spot treat weeds. Alternatively a hormone formulated as a powder and appropriately named Spot gives good results.

Some weeds are resistant to normal doses of hormones and need special treatment. These are mostly mat-forming plants of low growing habit which are not cut off by mowing. Typical examples include mosses of all sorts, pearlwort, speedwell, or veronica, yarrow, and yellow-flowered clover. Here the main control must be in the use of lawn sand, a good mixture of which can be made up with:

- 2 parts by weight sulphate of ammonia.
 1 part by weight sulphate of iron.
 13 parts by weight LIME FREE sand.

Where moss is the most prevalent weed, to the mixture should be added sufficient superphosphate to give 1 oz. of it per sq. yd. for the area to be treated. A hundredweight of the lawn sand plus superphosphate can be made up for about 21s. and is sufficient to treat about 450 sq. yds. at 4 oz. per sq. yd.

Applications to patches of the weeds should be made when the turf is damp and there is the prospect of fine weather. If a period of drought follows, an application then water should be applied to avoid serious scorching. Repeat the treatment as necessary throughout the growing season. Linked with this "spot" treatment, the growth of grass must be encouraged, as this will tend to smother low growing weeds. Thus, in the early spring when the turf is wet, feed with a

mixture of equal parts of superphosphate sulphate of ammonia and dry soil at 2 oz per sq yd over the whole area and repeat after a month if desirable. In addition do not shave off the grass by close cutting instead the blades of the mower should be set reasonably high for a whole season.

Where fertility is low clovers often predominate in turf. The Dutch clovers with white—or pink—flowers and a white angled band towards the base of each leaflet can be eradicated with Mecoprop. Afterwards the turf should be fed with nitrogenous fertilisers like soot and sulphate of ammonia to discourage reinfestation. Other types of clover found in turf are species of *Trifolium*. Compared to the Dutch clover these have a tight bunched habit of growth and yellow flowers. All of them are resistant to hormones and in addition to manual treatment should be treated with lawn sand.

Lakes—It sometimes happens that aquatic plants with large floating leaves such as water lilies get out of hand. Here control can be established by cutting off the foliage with a long handled appliance like the Corryu Water Scythe. The work should be done early in June and repeated as often as any fresh growth is seen.

Bulrushes are difficult to eliminate but can be destroyed by digging out the roots when the level of the water permits. Dalapon has been found to give a control application should be made with a wetting agent added when the rushes reach maturity.

Ponds—Problems of weed control in ornamental ponds are often not easy to solve. Where duckweed is prevalent this small floating plant can be eliminated by sweeping the surface of the water at regular intervals. If this practice is carried out thoroughly much of the vegetative growth will be eliminated and the plant will not be able to form resting bodies whereby it overwinters. Once a control has been established further spread of the plant can be prevented by introducing a few moorhens or ornamental ducks.

The most common of unwanted plants in pools is blanket weed. There is no single means of dealing with this plant for its spread is governed to a certain extent by unbalanced plant and animal life in the water. With this fact in mind water lilies should be established so that their foliage shades about 25 per cent of the water. In addition a few oxygenating plants should be introduced from local ponds or streams and a supply of goldfish added. Blanket weed is usually found in pools where the water gets over heated in summer for this reason the average depth of garden ponds should be a minimum of 2 ft and preferably a minimum of 3 ft.

Rose Beds—A complete control of annual weeds among roses can be obtained with Simazine. Here the salient point is to apply the herbicide immediately after pruning in March before any weed growth starts. Alternatively Diquat can be used in April or early May and the application repeated as necessary.

Shrubberies—With a shortage of labour beds of shrubs are often weed infested. Perennials can be eradicated with Diquat and annuals controlled by this treatment as they appear. Alternatively once the perennials are removed, the ground can be kept clear with Simazine used in the early spring.

Much to check weeds in shrubberies can be done by mulching the surface of the soil with heavy dressings of peat fallen leaves or sawdust. If the weeds push through the mulch a second application should be made at once.

Vacant Ground—On land free of crops all plants can be killed by watering the herbage with sodium chlorate at 1 lb to a gallon of water. In some cases repetition may be necessary. When using this method it should be remembered that treated ground will remain toxic to plant life for a period of up to six months. If doubt exists about the persistence of the chlorate in the soil, then it is advisable to wait for the appearance of annual weeds before planting.

Apart from its persistence, sodium chlorate is prone to seep through soil and affect plants for some distance away. To avoid danger of fire

from clothes being soaked in a solution of the chlorate and then dried it is prudent to use a formulation with an additive to reduce the risk of fire (See Finding List). Where couch grass is predominant then the best control is to be obtained with Dalapon.

SPECIAL PROBLEMS OF WEED CONTROL

Bindweed—Probably the most ubiquitous of all garden weeds. Up to the present time the main control has been to carefully fork out the roots as new growth is seen. If this is done methodically the plant can be eliminated within a reasonable time.

Lately chemicals have come to the fore and bindweed may now be eliminated by watering or painting the foliage with a formulation of 2 4 D when the annual growth has nearly reached maturity. Thus first applications can be applied in July and the treatment repeated if necessary to good effect. Where the weed is among cultivated plants the herbicides must be applied with a paint brush or the foliage rubbed with a cloth damped in a solution. When doing this rubber gloves should be worn.

Blanket Weed—See Ponds

Bracken—Horticulturally control is not a big problem and in limited areas it is easily dealt with by repeatedly cutting the aerial stems with a grass hook as the first fronds open. This practice will exhaust the underground food supply of the plant and gradually it will die out. The young fronds are rich in plant food and while still green and fresh they should be composted. No chemicals will offer a reasonable control of this plant and, indeed, it is best dealt with by cutting and final digging out of the roots.

Couch Grass—Where the soil is light and tends to be low in fertility it is often found that this is a difficult plant to eradicate by cultural means. If the long underground stems are forked out in the conventional manner and left on the surface to dry the roots may be composted to advantage and a good control established. To prevent reinfestation, manures and fertilisers should be applied generously and the ground kept hoed regularly. Chemically couch grass can be killed easily by watering the foliage with Dalapon.

Ground Elder—Without question this is one of the worst garden weeds and whether or not the fact is pleasant or acceptable it is indubitably a weed of neglected ground. In varying degrees it is resistant to hormone weed killers of all sorts. On ground free of crops it may be reduced by an application of sodium chlorate as explained in the paragraph Vacant Ground. The first treatment should be made as soon as growth starts in the spring and repeated if the desired effect is not abundantly clear. When ground elder is to be found among herbaceous plants the cultivated plants must be lifted out and the weed removed by repeated hand forking.

In shrubberies reasonable control can be had by smothering the young growth in the spring with a thick dressing of peat leaf mould baled straw or sawdust. If growth penetrates the surface dressing it will be found that the etiolated shoots are not difficult to remove by hand or a second layer can be applied to complete the treatment.

Alternatively the foliage of ground elder can be watered with Diquat and the treatment repeated once or twice during the growing season.

Horsetail—This is sometimes erroneously called mare's tail and on poor sandy soils it is often a common weed. Fortunately recent experiments have proved that it can be easily controlled by spraying or painting the mature growths with a formulation of 2 4 D taking care of course to keep the spray off cultivated plants near by. As the appearance of horsetail is symptomatic of low fertility manual treatment should be carried out on a generous scale. Where the weed is growing among cultivated crops individual stems must be treated separately as recommended for bindweed.

Mare's tail—See Horsetail.

Moss — See Lawns (T33)

Nettles — It is difficult to understand why the perennial nettle is so abundant as it is immediately responsive to applications of 2 4 D and 2 4 5 T made any time during the growing season.

The annual nettle is usually proved a denizen of rich, light soils and may be eradicated with cresylic acid Diquat or 2 4 D.

Oxalis — Of all weeds this is probably the most difficult to destroy. It is easily identified by its large trifoliate leaves like that of clover. Unlike other weeds oxalis cannot be efficiently removed by hand as this disturbs the bulbs clustered around the base of the stem of mature plants. On ground free of crops sodium chlorate can be applied in March (see Vacant Ground). Perhaps a second application may be necessary but even so control may not be complete. Among shrubby plants it may be possible to eradicate the weed by smothering as suggested in the paragraph on ground elder.

The foliage can be killed with Diquat and by repeated applications this may constitute the best means of control.

Speedwell — See Veronica

Veronica — This procumbent blue flowered weed of turf is sometimes known as speedwell. Being resistant to hormones its control may only be established with lawn sand. See also Lawns.

Woody Plants — With or without the addition of 2 4 D these may be killed with 2 4 5 T. This hormone is particularly useful on bramble, gorse, ivy and other unwanted shrubby plants. It is necessary to thoroughly saturate the foliage of deciduous trees and the best results are obtainable when the leaves are fully mature but not starting to die off. In the case of ivy the dormant shoots should be generously sprayed for the best results.

Yarrow — A weed found in many lawns where its presence often signifies low fertility. Control is with lawn sand. See Lawns (T33).

Summary — From these notes it will be seen that there are many aids for dealing with weeds. The salient point is to get the right method for each plant. Equally important is to check the reason why certain weeds grow profusely under some conditions. Very often this natural tendency can be counteracted as in the case of phosphate fertilisers against moss and in the application of organic manures and chemical fertilisers where horsetail and yarrow are concerned. See T35.

FINDING LIST FOR WEEDKILLERS

All the herbicides in this list are first-class chemicals which have been approved by the Ministry of Agriculture and are available in small packs designed for use by amateur gardeners. In case of difficulty in obtaining any of them the manufacturers should be contacted.

The list may appear unnecessarily long but the pipe dream of multipurpose herbicides is not a reality and the full extent and value of chemical weed controls are only obtained by using herbicides for their specific purposes as such they constitute an efficient and economic method of eradicating unwanted plants of all sorts

Trade names	Chemicals	Manufacturers	Type of action	Plants controlled	Notes and precautions
WEED KILLERS FOR USE ON TURF					
Bugges 2 4-D	2 4-D	Bugges Insecticides Ltd Sittingbourne Kent.	Hormone growth regulator trans located throughout the plant	Many broad leaved weeds and some perennials ones Best	Primarily for use on lawns Beware of drift.
Dicotox		May and Baker Ltd Dagenham Essex		hormone type for killing daisies dan delions and plan tains	
Shell Weed kill		Shell Chemical Co Ltd			
Lernox		Boots Pure Drug Co Ltd			
Bugges M O P A.	M O P A.	Bugges Insecticides Ltd Sittingbourne Kent	Hormone growth regulator trans located throughout the plant	Many broad leaved weeds and some perennials ones Best	Primarily for use on lawns Beware of drift on small areas the powdered formulation in puffer pack can be used
'Weed a Lawn' and Spot (in powder form)		Pan Britannia Industries Ltd Britannia House Waltham Cross Herts		hormone type for killing creeping buttercup Useful against pearlwort with repeated applications	
Olovotox	Mecoprop	May and Baker Ltd Dagenham Essex	Hormone growth regulator trans located throughout the plant	Best control for white flowered clover chickweeds and field woodruff Use full against pearlwort with repeated applications	Primarily for use on lawns Beware of drift
Lawn sand	See T33(2)	Usually home made	Scorching of annual growth Of herbicidal and manual value in most cases	invaluable against weeds resistant or semi resistant to hormones like pearlwort moss veronica (speedwell) yellow flowered clover and yarrow	See Lawns (T33(2)) for detailed information
Velves Lawn Sand		Pan Britannia Industries Ltd Britannia House Waltham Cross Herts.			The use of calomel dusts should be confined to mosses of no manual value
pbi Calomel Dust					

WEEDKILLERS FOR GARDEN USE

Nova Soil Steriliser	Cresylic Acid	The Murphy Chemical Co Ltd Wheathampsted St Albans Herts	Contact herbicide	For destruction of growth of annual weeds and top growth of perennials	Particularly valuable on asparagus beds and where annual weeds have to be controlled Also used as a soil sterilant.
Bugges Dalapon	Dalapon	Bugges Insecticides Ltd London Rd Sittingbourne Kent	Trans located throughout the plant killing vegetation by movement from leaves to roots	Annual grasses couch grass sedges reeds and bulrushes	Delay planting for 40 days after application. May be used upon makers instructions as a selective herbicide on asparagus shrubberies, fruit gardens, etc
Weedol	Diquat Salt	Plant Protection Ltd Yalding Kent	Trans located throughout the plant but with scorching effect similar to contact herbicides	Kills annual weeds and top growth of perennials One of the few herbicides to give a good control of ground elder Selective only by application, i.e kills all foliage it contacts	Undoubtedly one of the most valuable and interesting herbicides to be introduced Inactivated upon contact with soil no residual effects Available in small packs Can be stored from season to season.
Fath Weed Control Weedex	Simazine	Boots Pure Drug Co Ltd Fisons Horticultural Ltd Harvest House, Feltham Suffolk	Soil acting killing seedling vegetation by uptake through roots	Controls germinating seeds of many weeds over a long period	Apply when ground is wet in early spring on asparagus, apples pears (not plums) soft fruit, ornamental trees, and shrubs including roses. Slow acting
Polybor-Chlorate	Sodium Chlorate	Borax Consolidated Ltd Borax House Carlisle Place SW 1	Trans located throughout the plant and soil acting	Toxic in varying degrees to all plants except mosses The best chemical for killing tree stumps	To a large extent superseded by other chemicals Can be used on paths, drives and vacant ground
Boots Bramble, Brushwood and Nettle Killer	2,4 5-T	Boots Pure Drug Co Ltd Station Street, Notting ham.	Hormone growth regulator trans located throughout the plant	Special value in control of woody plants like brambles, brushwood and ivy Also good against nettles.	Beware of drift

GAMES & RECREATIONS

ENTP+LL

1970

Indoor and outdoor games and
leisure activities, alphabetically
arranged, together with 4 pages
of records, including the 1968
Olympic Games, the 1969
European Championships and
the 1970 British Commonwealth
Games

GAMES AND RECREATIONS

PEOPLE have always been fond of playing games and of thinking out ways of spending their leisure time and of celebrating special occasions. The result is a long history of games recreations and customs some of which are described in this section. The arrangement is alphabetical.

One problem that confronts those keen to try some game or recreation is how to set about it. In many cases the simplest way of finding out what facilities exist in a particular area is to enquire at a local newspaper office which will have particulars of all sports clubs, dramatic societies and other recreational bodies in the area. A few addresses that might be useful to those with certain specialised interests appear at the appropriate places in the text, and a valuable source of helpful information on many games and recreations is 'the Central Council of Physical Recreation, which has English, Welsh and Northern Irish addresses as follows: England 28 Park Crescent London W1N 4AJ, Wales 47 Cathedral Road Cardiff, and Northern Ireland 49 Malone Road Belfast. The Scottish Council of Physical Recreation is at 4 Queensferry Street Edinburgh 2. Those keen on touring the country at moderate cost might appreciate the services provided by the Youth Hostels Association which has addresses as follows: England and Wales Trevelyan House St Albans Herts with a London office at 29 John Adam Street W C 1, Scotland 7 Bruntsfield Crescent Edinburgh 10, Northern Ireland 28 Bedford Street Belfast and the Irish Republic 39 Mountjoy Square Dublin.

American Football.

American football is played eleven a side on a pitch marked by a line across every 5 yards and with goals and a ball resembling those used in rugby football (q.v.) though the ball is smaller. Scoring is by touchdowns which are like Rugby tries but count six goals after touchdowns which count one field goal during play which count three and safeties which give the attacking side two points if the defenders carry the ball over their own goal line and touch it down. The ball is advanced by carrying it forward passing and kicking. The game consists of a series of plays or downs the ball becoming dead when the ball carrier is tackled. A team must advance 10 yards in four downs or give up the ball to their opponents. Players can run ahead of the ball carrier to protect him by blocking opponents. Penalties take the form of distance usually 5 or 15 yards lost. A game lasts 60 minutes divided into four 15 minute quarters.

Angling

Angling which is catching fish with rod, line and hook goes back to beyond the beginning of history for it was known to the Greeks and Romans. It is now a recreation for though the catch may subsequently be cooked it is not primarily fishing for the pot. It has its competitive side with competitions offering prizes for the biggest catch and there are angling clubs but many people prefer to use it as a recreation to be enjoyed alone in quiet surroundings. It is actually not so much a recreation as many recreations for fishing can take place in the sea, rivers, lakes, ponds and even canals and there are several entirely different kinds of angling. The most obvious divisions are fresh water fishing including coarse and fly fishing and sea angling including fishing from piers and the shore and big game fishing.

The biggest branch of angling is fresh water fishing for general or coarse fish which are so called to distinguish them from game fish like salmon. Coarse fishing is bait fishing or in the case of pike spinning groundbait also being thrown in before and during fishing. It covers many varieties of fish and the bag may be a very mixed one. Certain fish of course are known to frequent certain localities or types of locality but though the angler may know exactly the kind of fish he is after he rarely knows if his catch will consist entirely of that kind of fish or even if it will include any of that kind. Coarse fish do not generally make good eating.

Fly-fishing for salmon and trout differ widely from coarse fishing and from each other. As the name implies artificial flies are used but those used for trout are quite different from those that

attract salmon. In the case of trout a fly is made to resemble a real insect as closely as possible but with salmon this is not necessary. Salmon rarely if ever feed in fresh water and when in that type of water they are usually irritable. They will dart wildly at any objects that attract their attention so salmon flies are simply bright objects designed to draw them on. Fly fishing is rather an expensive sport for it means hiring beats on private water. In both coarse and fly fishing the angler would be well advised to keep out of sight of the quarry as much as possible.

Sea angling is now the most competitive form of angling with sea angling festivals and competitions plentiful during the holiday season. It has what might be called its equivalent of fly fishing with feathers which attract several kinds of fish.

Big game fishing takes place from a motor launch which is not towed by the hooked fish but follows it so that the ensuing fight is between man and fish and not between the fish and the dead weight of the boat. Such a fight could last for 12 hours and it is never certain that the angler will win it. Tunny is the only big game found off the British coasts.

Archery See Old English Games and Customs

Association Football.

Games that may have resembled football were played by very ancient races and games that certainly were football of a kind were played in the England of several centuries ago but the Association football that is the most popular game in Britain and perhaps the world to day had its origins in the games played at English Public Schools in the days before sport became organised.

It was not surprising that some of those who had played football of one kind or another at school should want to go on playing after they left but before they could do so it was necessary to work out a set of rules that would be universally understood and accepted. Meetings were organised by those interested and as the universities were natural meeting places for boys from many schools it was there particularly Cambridge that these took place.

It was soon evident that there was a major difference of opinion between those who wanted handling permitted and those who opposed this. The rival factions proved irreconcilable so they went their separate ways. The handling enthusiasts based their rules on those in force at Rugby School and thus pioneered rugby football (q.v.). Those who felt that football should be played primarily with the foot brought into being the game that was to take its name from the Association that was formed, in 1863 to govern it.

and became Association football often called
by the abbreviation soccer

U3

He cannot however be offside in his own half from a corner kick or from a throw in. If a player in an offside position interferes with the game a free kick is awarded.

A game is controlled by a referee who has the assistance of two linesmen. These may signal infringements, but the referee is not bound to act on such signals.

In Britain soccer is a winter game the season lasting from August, until May though in Scotland it continues even during the short summer season in the form of five a side football known as the short game British soccer is highly organised ranging from the fully professional Football League of four divisions and the equivalent though slightly smaller Scottish League through minor professional leagues to amateur leagues There are also many cup competitions from the Football Association

Challenge Cup Football League Cup and the Scottish Cup downwards

The game has also spread all over the world being extraordinarily popular in Europe, Asia and South America and played to some extent almost everywhere else. There is a World Cup competition that is played for every four years, a European Nations Cup played for every two years and an annual European Champion Clubs Cup competition played for by the top league club of almost every European country and a European Cup winners Cup Soccer is also included in the Olympic Games.

Athletics.

The sport of athletics which includes running walking, jumping and throwing is probably the most natural of all sports and certainly one of the oldest.

Modern athletics can be said to have begun in 1848 when the Royal Military Academy instituted a meeting that was followed by a similar meeting at Exeter College Oxford and subsequently at other Oxford and Cambridge Colleges. The Civil Service were also early in the field and the first athletic club was the Mincing Lane Athletic Club now the London Athletic Club. There was also the Amateur Athletic Club which organised an annual championship meeting and acted as a governing body for both athletics and amateur boxing.

In 1880 the Amateur Athletic Association was formed as a governing body. Other countries, particularly the United States, took to the sports and in 1896 the first modern Olympic Games were held at Athens. Other international meetings and matches followed and championships and competitions of all standards were started in many countries. Women came into the sport in the early 1920s and were included in the Olympic Games in 1928. There is now a long list of inter-

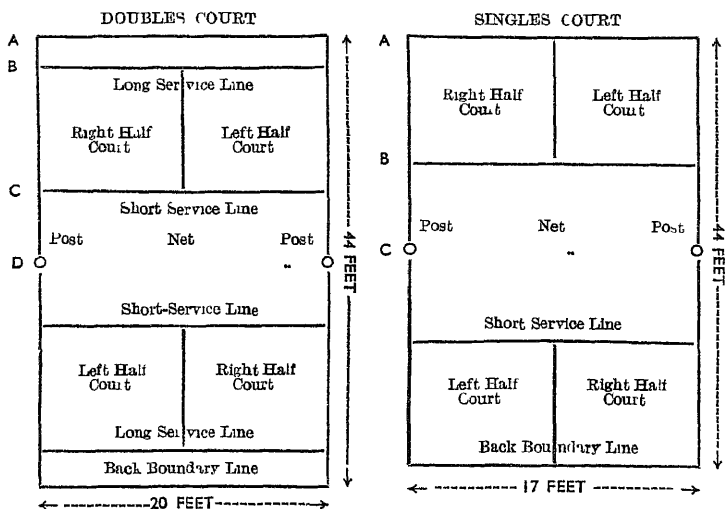

nationally agreed standard events including distances measured in yards and miles and also their metric equivalents and including also a major all round test the ten event decathlon

The longest strictly standard distances are the marathon of 26 miles 385 yards for runners and 50 000 metres for walkers but there are regularly held longer events For runners the longest annual race is between Durban and Maritzburg about 55 miles the longest in Britain being from London to Brighton about 53 miles but there are occasional 100 mile and 24 hour events For walkers there are annual 100 mile races and fairly regular 24 hour ones

The marathon commemorates the run of the

Australian Rules Football

Australian Rules football is played 18 a side on large oval grounds At each end there are four posts seven yards apart and scoring which is high is by goals counting six points when the ball is kicked between the two inner posts and behinds counting one point when it is kicked between the outer ones The ball resembles a rugby ball but is less pointed Players must not run more than 10 yards with the ball without bouncing it or touching it on the ground The ball must not be thrown but it can be passed by holding it with one hand and punching it with the other or by kicking Players in possession can be tackled between the shoulder and the knee or

NOTE—If it is practicable place the posts on the side boundary lines failing this place them at any distance not more than 2 ft outside these lines

coumer Pheidippides from the battlefield at Marathon to Athens carrying the news of victory over the Persians (490 B.C.). This run covered about 25 miles but the distance was standardised at 26 miles 385 yards in the 1908 Olympic marathon from Windsor to the White City London. All marathons commemorate the Battle of Marathon but the oldest annual marathon the Boston marathon also commemorates the Battle of Lexington (the first battle of the American Revolution) and more particularly the ride by Paul Revere that preceded it

Cross Country. Athletics is mainly a summer sport but in cross country running it has an extremely popular winter branch.

Cross country originated in the traditional runs at various English Public Schools particularly Rugby and Shrewsbury and came into wider prominence when it was adopted by the Thames Rowing Club as winter training. It is still used as training by many sportsmen of all kinds but it is now also a thriving competitive sport in its own right. There is an International Championship but this is not yet fully representative being virtually confined to Western European nations. Major cross country championships are over courses of 9 or 10 miles

charged. There is no offside and no scrummaging. A game consists of four 25 minute quarters. The game has existed since 1858 and is played to the practical exclusion of all other forms of football in the southern half of Australia and in Western Australia. There are over 3 000 clubs.

Badminton

Badminton might be described as an indoor version of lawn tennis (qv) in that it is played over a net and can consist of either singles or doubles. There however the resemblance ceases. Only the serving side can score. If the server wins the rally one point is scored. If he loses the next player serves. A game is won by the side first making 15 points (11 for women). Three games make a set. The shuttlecock or bird is a small cork hemisphere in which feathers are fixed. All shots are volleys. The major tournament which has been held for over 70 years is the All England Championships.

Bandy. See Skating

Baseball

The invention of baseball a summer game played from April until October and the national

game of the United States is generally credited to an Army officer its origins being old country games called One Old Cat and Two Old Cat.

Teams are nine a side and bat and field in turn. The main part of the ground the diamond has a base marked by a sack at each corner the lines from sack to sack being the base paths. One base is home and there the batter stands, by a square of rubber on the ground called the plate. The base forward and to the right of a right handed batter is first the one straight ahead of him is second and the one forward and to his left is third the distance from one base to the next being 30 yards 20 yards out straight in front of the plate is the pitcher's mound. The lines from home to first and from home to third are continued beyond these bases and are the foul lines.

It is the object of the batting side using a bat which resembles a long heavy Indian club with which to hit a hard white ball weighing 5 ounces to score runs one being scored each time a player completes a circuit of the bases not necessarily from one hit. When a batter leaves the plate either out or to proceed along the base paths the next man comes in the team 5 innings lasting until three men are out. Nine such innings complete the game and in each innings the batting side carries on at the point in the batting order reached in the previous innings. There is no toss for first innings the visiting side always batting first.

The pitched ball reaches the batter without touching the ground and if not hit it should pass over the plate between the batter's shoulders and knees. If it does so it is a strike and three such strikes dismiss the batter. If it does not it is a strike only if the batter swings at it. Other wise it is a ball and four balls give the batter a free passage to first base called a walk. A batter also walks if he is hit by a pitched ball. Other ways in which the batter can be dismissed are by being caught and by being put out while on the base paths by failing to reach the base to which he is running before the ball. When an out is made the ball does not become dead. If there is more than one runner on the base paths then if the ball can be relayed quickly enough two or even three men can be put out on the same play.

If the batter hits fairly he must run but to be fair the hit must be in front of him and between the foul lines. A foul hit counts as a strike against him, except that the third strike which actually dismisses him must be a clean one across the plate. If a foul is caught he is out.

The fielding side is divided into three sections, the battery the infield and the outfield. The battery consists of the pitcher and the catcher who stands behind the plate and gives signals indicating the kind of ball he thinks the pitcher should deliver. For though the pitched ball does not touch the ground, pitchers can produce a wide variety of deliveries, including various kinds of curve. The infield consists of the first baseman at or near first the second baseman, between first and second the short-stop between second and third and the third baseman at or near third. The outfield covers the ground beyond the infield the three remaining fielders taking the right centre and left sections of it. Catchers wear a large glove on the non throwing hand a mask a chest protector and leg guards. All the other fielders wear a glove on the non throwing hand the first baseman's being larger than the others. The batter wears no protective gear.

Substitutes are permitted pitchers frequently being changed if they are being hit and pinch hitters being sent in instead of weak batters if a hit is desperately needed. If this happens, the man replaced often the pitcher cannot return when his side fields again, though his field replacement need not be the man who batted for him.

As with cricket (q.v.) batting averages are recorded these being calculated by dividing the number of times at bat into the number of hits. An average of 0.400 referred to as four hundred would be exceptionally good. Hits mean

safe hits on which the batter achieved one or more bases without giving a chance. If he reaches base because a catch was dropped or a ball mis-fielded he plays on from there in the usual way but is not credited with a hit. Pitchers are graded according to the number of games won and lost. Recorded fielding statistics include each man's put outs assists which are throws from which a team mate made a put out and errors.

In the United States there are clubs and leagues of all standards from professionals of various classes through semi professionals to amateurs called sandlotters and boys. The top class of all consists of two major leagues the National and the American each with eight clubs. The champions of these two leagues meet in a best of seven games series for the Championship of the World always known as the World Series.

Baseball is also the chief summer game of Canada and it is quite widely played in some other countries including Australia Britain and Japan.

Softball similar to baseball is popular in the United States with women as well as men. The ball is not particularly soft but it is larger than a baseball and pitching is under arm. Distance between bases and between the plate and the mound are shorter than in the parent game. A modern adaptation is played with a 12 lb ball a light plastic wheel that has a swerve in flight when delivered like a quon.

Basketball.

Basketball was invented in 1891 by an American YMCA official at Springfield Massachusetts as a winter team game that could be played indoors. It can be played in almost any gymnasium or hall and it can also be played outdoors on an asphalt court. In America it is played by teams of all standards from schoolboys to professionals and it is watched by more spectators than any other game. It has now spread to many other countries and is included in the Olympic Games. It has been established for some years in Britain where it has been encouraged by the Services and the YMCA.

Basketball is played five a side substitutes being permitted with a ball resembling that used in Association football and goals consisting of a net or basket suspended from a metal ring attached 10 ft above the floor to a back board. It is purely a handling game and the ball is advanced by dribbling which means bouncing and by passing. Deliberate bodily contact is not allowed. Goals thrown during play count two points and goals thrown from free throws after infringements one point. Height is an asset in the game which demands stamina and agility and which has been highly recommended as an ideal training activity by coaches of other sports particularly athletics (q.v.).

The Amateur Basket Ball Association with some 9,800 registered players in 670 clubs governs the sport in this country. Men and women have their local area or county associations and mini basketball with modified rules for under 12s is becoming increasingly popular in the schools.

Biathlon See Winter Sports

Billiards

Billiards, which originated in France is a game of angles and of very great skill. It is played on a table measuring 12 feet by 6 feet 1½ inches having six pockets, one at each corner and one in the middle of each side. The table is covered with green baize the edges being of cloth-covered rubber called cushions. Across the table 2 feet 5 inches from the bottom edge is a line called the baulk line the space between the line and the bottom of the table being the baulk. On the baulk side of the line there is a semi-circle with a radius of 1½ inches from the centre of the line. Down the centre of the table are four

spots one 121 inches from the top one mid way between the top and the centre one in the centre and one in the middle of the baulk line. Two white balls one with a spot for identification purposes and one red one are used the balls being played with cues that taper down to a striking tip. The remaining equipment includes a long cue like stick with a metal cross fixed diagonally on the end called a rest or jigger and a special long cue these being used when the player cannot reach his ball in the ordinary way. Most games are singles though doubles can be played, the object of the game being to score points according to fixed rules an agreed number of points making the game.

To decide who is to start players string by playing their balls simultaneously from baulk up to the top cushion the ball which returns nearer to the bottom cushion winning. At the start the red ball is spotted on the top spot and players start from the baulk circle. Scoring is three for pocketing or potting the red or going in off the red, two for potting the white which is of course the opponent's ball or going in off the white and two for a cannon which is hitting both the other balls. A player whose shot hits no other balls at all gives one point to his opponent unless his ball goes into a pocket when he forfeits three. A player's turn called a break continues as long as he is actually scoring. When the red is potted it is immediately respotted.

Snooker Also played on a billiard table and perhaps even more popular is snooker, which uses 22 balls positioned as follows: 15 reds in the form of a triangle with its apex on the second spot from the top and its base at the top end, a black on the top spot, a pink touching the apex ball of the triangle, a blue on the centre spot, a brown in the middle of the baulk line with a green beside it on the left end of the baulk circle, and a yellow on the right end and a white which is the cue ball to be played. The points values of the balls are from one for red through yellow green brown blue and pink to seven for black. A player's turn continues as long as he scores his first shot being at a red when if he pots one he plays at one of the other colours play being at reds and colours alternately as long as balls are being potted and as long as there are reds on the table after which the remaining colours are played in ascending order of value.

A variation of snooker is snooker plus. This uses two additional balls, an orange placed between the pink and the blue and valued at eight points and a purple placed between the blue and the brown and valued at ten points.

Pool Russian Pool and Pyramids Other games played on a billiard table include pool Russian pool and pyramids. In pool each player has a ball of a different colour the order of play being white red yellow green brown blue pink black. Each player plays at the ball of his predecessor and tries to pot it the game starting with white spotting his ball on the top spot so that red is actually the first to play. A player whose ball is potted loses a life players losing three lives dropping out of the game. A turn continues as long as a player is potting balls and if he clears all the balls on the table he then spots his own ball for the next player.

Russian pool uses the yellow green blue and black balls with the white as cue ball the black being placed on the top spot the blue on the centre spot the green on the left side of the baulk circle and the yellow on the right side. A player's first shot must hit the black after which he can play at will. Scoring is by potting balls, by going in off balls and by cannons but the black can be used only for the top pockets the blue for the middle pockets, and the green and the yellow for the bottom pockets. Cannons count two potting or going in off counting nine for the black seven for the blue five for the green and three for the yellow. A player's turn continues as long as he is scoring but consecutive cannons on the same balls are limited to 25 and the same ball must not be potted from the same spot more than three times in succession. A complete miss forfeits

three points. A variation of Russian pool adds the pink ball which is spotted on the second spot from the top counts six and can be used with any pocket.

Pyramids uses the 15 reds starting in their triangle and a white cue ball the object being to pot the reds. A turn continues while a player is scoring 8 balls potted ending the game.

Boat Races

Race rowing is a strenuous sport that makes no pretence of attracting as many active participants as some other sports and games yet its long history includes races with unusual stories about them races that are amongst the greatest annual international sporting events and one race that provides what is probably the most enthusiastically supported free sporting spectacle in the world.

That of course is the Oxford and Cambridge University boat race rowed on the Thames from Putney to Mortlake. First rowed in 1829 it has offered its excited public which includes thousands of people with no connection of any kind with either university everything including runaway victories dead heats and even sinking boats. To all intents and purposes this is a regular annual event and has been so since 1856 but in actual fact every race is the result of a separate special challenge from the losers of the previous race to the winners of it. The race has an interesting parallel in the United States where Yale University whose colours are dark blue annually meet Harvard University which is at Cambridge on a river called the Thames.

The Oxford and Cambridge race is the best known annual race on the Putney-Mortlake stretch of the Thames but it is by no means the only one. There are other races that attract entries sometimes numbered in hundreds entries that are far too big to race abreast on the Thames and so race in single file with crews following each other at fixed intervals in what are known as the Head of the River races. The biggest of these is for crews of eight but there are other Head of the River races for women's crews who cover only part of this famous stretch of water and for single scullers. Single scullers also cover this course in a straightforward race in the Wm. field Sculls event which ranks as the English Amateur Championship and which was first held one year after the first Oxford and Cambridge race in 1830.

Head of the River races but with a difference are also held between the colleges of Oxford and Cambridge where the Isis and the Cam respectively are much too narrow to permit straight forward racing. These are the Bump Races in which each crew endeavours to catch and bump the crew ahead of it except for the leading crew which can concentrate on staying in front. When a bump is achieved the two crews pull into the bank and change places for the next day's racing. The racing goes on for four days and it is of course the ambition of each crew apart from the leaders to register a bump on each day.

Back on the Thames but farther down it towards the port and docks of London is the scene of a race that makes the Oxford and Cambridge race and the Wingfield Sculls look like recent innovations. This is the annual race from London Bridge to Chelsea for the Doggett's Coat and Badge a single sculling event open only to young watermen who are within twelve months of completing their apprenticeship. It was founded in 1715 in honour of the House of Hanover and to commemorate the anniversary of King George I's happy accession to the throne of Great Britain. By Thomas Doggett a Dublin born actor connected with the Drury Lane and Haymarket theatres who regularly travelled on the Thames in preference to using the roads, and who left a sum of money to perpetuate the race which is now controlled by the Fishmongers Company.

BOXING

This race is more truly an annual one than almost any other event. For while most so called annual races have been subjected to long interruptions because of the two World Wars those qualified for the Doggett races during those years were subsequently traced and the races duly decided after the wars. The event is a colourful one always followed by a barge carrying a batch of past winners wearing the Coat and Badge and also the cap breeches silk stockings and buckled shoes that go with them. The scarlet pleated quilted Coat with its silver buttons and the large silver arm Badge bearing the White Horse of Hanover and the word Liberty are presented at the Fishmongers Hall where the winner is greeted with a salute of trumpets and the tune 'See the Conquering Hero Comes'.

For a rowing event of a very different kind dating back only to 1830 one must go up the Thames far beyond the end of the Tideway to Henley for the annual Royal Regatta. This consists of events open to the world and others closed to English colleges and schools for eights fours pairs double sculls and single sculls the most famous of its races being the Grand Challenge Cup for eights and the Diamond Sculls.

Soon we are to have our first 2000 metre international rowing course at the National Water Sports Centre Holme Pierrepont near Nottingham. It has been made possible by a Government grant through the Sports Council and will be administered by the Central Council of Physical Recreation.

Competitive rowing in this country is governed by the Amateur Rowing Association 160 Gt Portland St London W1N 4TB.

Bowls

Bowls one of the oldest of all games, was once regarded as an old man's game, but it actually has many devotees of all ages and both sexes, and is played indoors as well as outdoors. It certainly goes back to the thirteenth century when its popularity made it one of the games legislated against as likely to draw people away from archery. Henry VIII played and the famous game on Plymouth Hoe in which Sir John Hawkins stayed to beat Sir Francis Drake even after the Armada had been sighted, if not definitely authenticated is accepted as fact by several historians. It is interesting to note that if this game was played, it would have been almost identical with a game of to-day for it was in that century that the bias that is a leading feature of the bowls or woods was introduced. A century later however Bowls which was largely played on greens attached to taverns, acquired a reputation as being merely an adjunct to pot house revelry but it was revived on a higher level in Scotland, and never again came so near to oblivion.

The English Bowling Association 2 Roseford Road Cambridge is on the International Bowling Board.

There are actually two games of bowls, the rink or level green game and the crown green game and it is the rinks rather than the objectives that differ. The level green game is the more widely played, and it takes place on a perfectly flat piece of well-cared for turf. The crown green game which is popular in the North and Midlands is played on a green of which the centre is 6 inches or more higher than the corners. The games differ—for instance in the putting into play of the object ball—but only slightly so it will be appreciated that the crown green game demands a good deal of experience and skill. It is mainly a singles game whereas the level green

U7

GAMES AND RECREATIONS

game is played between sides consisting of one, two three or four players.

Bowls looks a simple game the object being simply to place the bowls as near as possible to the object ball or jack. The bowls however are biased and the game is actually one of considerable skill. When bias was introduced it took the form of weighting with lead but it is now achieved by turning one side of the bowl less round than the other. Level green bowls weigh up to 3½ lb but crown green bowls are smaller and less biased. On the crown green however the jack which is played into position by the first player is also biased.

Players normally use two bowls in a game or four in singles and the side with the best record of bowls near the jack wins the end and the best record of shots in an agreed number of ends the game.

Bowls is also played on carpet rinks indoors and the new multi sports centres usually cater for it.

The French play their *pétanque* or *boule* on gravel sand or any other such surface with steel bowls which are thrown as well as rolled at a wooden jack or *cochonnet*.

Boxing

Boxing sometimes called The Noble Art of Self Defence though actually aggression is its keynote and defence an incidental is a modern continuation of the old sport of prize fighting which though always illegal was popular from the time of the Regency until it was succeeded by the present day glove fighting at the end of the nineteenth century.

In prize fighting bare fists were used and wrestling holds were allowed. Rounds ended when a fighter went down, and fights continued until following a knockdown a man failed to come up to the scratch line in 30 seconds.

In modern boxing gloves are worn, and no wrestling is allowed. Rounds last for a fixed time generally 3 minutes with 1 minute between rounds and fights last only for a fixed number of rounds never more than fifteen. A knockdown does not end a round the man who is down having 10 seconds in which to rise. If he fails to do so his opponent wins by a knock out. If a man fails to come up at the beginning of a round or if the fight is stopped to save a man from further injury the victory is by a technical knock out. If however both men are still on their feet at the end of the stipulated number of rounds, a decision is given on points. Boxing is therefore technically a contest of skill for points, and, as such far removed from prize-fights to a finish.

Fights are controlled by a referee, and in British professional boxing he is solely responsible for any points decision. In amateur boxing the decision is given by several judges, who sit apart from each other. The difference between a good professional and a good amateur is probably more marked in boxing than in any other sport.

Boxing contests are arranged in classes according to weight the divisions being fly weight up to 8 stone bantam weight up to 8 stone 6 lb feather weight, up to 9 stone light-weight up to 9 stone 9 lb welter weight up to 10 stone 7 lb middle weight up to 11 stone 6 lb light-heavy or cruiser weight up to 12 stone 7 lb and heavy weight, any weight. In amateur boxing some of these weights are slightly different, and there are two additional classes light-welter weight, up to 10 stone, and light-middle-weight up to 11 stone.

Prize-fighting was governed successively by Broughton's Code the New Rules of the Ring, and the London Rules. Then, in 1867 the eighth Marquess of Queensberry and Mr J G Chambers drew up the rules that have been the

basis of boxing ever since. British professional boxing has been controlled since 1929 by the British Boxing Board of Control. The Amateur Boxing Association has governed amateur boxing since 1884 when it took over from the Amateur Athletic Club which had looked after both boxing and athletics.

Bridge

Bridge is probably about one hundred years old but though it clearly developed from Whist its exact origin is unknown. Similar games were played in Denmark, Turkey, Egypt and Russia and it first appeared in Britain as Dutch whist in 1884. It was subsequently known as Russian whist and biritch. Then in 1895 the first bridge rules appeared followed in 1903 by rules for a new version, auction bridge. A third version, contract bridge, was known before the First World War reached Britain just after it and acquired international rules in 1929. During the 1930s all three forms were played. The object of each succeeding version was to make the game less one of chance and more one of skill. Contract has now supplanted them all and this is the game we shall describe.

Two partnerships of two oppose each other and as the names auction and contract imply the playing of each hand is preceded by an auction in which players bid or refrain from bidding on the value of their hands to decide which pair will attempt to make how many tricks with what trumps or with no trumps.

The suits have different values, the order being spades, hearts (known as major suits), diamonds, clubs (minor suits) but no trumps takes absolute precedence.

Originally spades were the lowest suit and when spades had prevailed players took to throwing in their cards and giving the caller the points rather than play such a low scoring hand. To prevent this spades were given a value which made them the top suit.

A feature of the actual play is that the member of the pair whose bid prevails who first named the successful suit plays the hand alone, playing both his own cards and his partner's which are placed face upwards on the table after the first card has been played.

Bridge terms the beginner should know include *bid* an offer to make so many tricks in a particular suit or with no trumps; *auction* the bidding process; *contract* the last and prevailing bid; *forcing bid* a bid which forces the player's partner to bid and keep the auction open; *take out* a bid in a suit other than that bid by the player's partner; *system* or *convention* the bidding system used by a pair; *the book* the first six tricks won by a pair which do not count towards the contract—a bid of one means in fact seven; *declarer* the player of the pair whose bid prevails who first named the successful suit; *dummy* declarer's partner; *defender* during the auction a member of the pair which did not open the bidding; during play an opponent of the declarer; *game* 100 points; *rubber* two games won by a pair; *vulnerable* a partnership which has won a game becomes vulnerable; *overtrick* a trick won in excess of the contract; *undertrick* a trick by which the contract falls; *grand slam*, 13 tricks bid and won; *small slam*, 12 tricks bid and won; *trump* a card of the contract-suit; *raft* to trump; *tenace*, two cards not in sequence which may win two tricks, but may win only one; Other terms not peculiar to bridge include *void* no cards of a suit; *singleton* one card of a suit; *doubleton* two cards of a suit; *honour* ace, king, queen, knave or ten; *paraborough* a hand with no honours; *revolve* failure to follow suit when able to do so.

A bridge score-sheet has a line across it and points are scored above or below the line. Only points towards game go below the line, these being points for contracts made. Diamonds and clubs

count 20 per trick (over six) spades and hearts 30 and no trumps 40 for the first trick and 30 for each subsequent one. When a game is won points below the line revert to nothing. Above the line go points for tricks won in excess of the contract for tricks by which opponents fail to make contracts for winning a rubber for slams (if bid) and for holding four aces in no trumps or four or five honours in a trump suit in one hand. Being vulnerable affects the points as does the fact that bids may be doubled by opponents then redoubled by the bidding pair. It might seem that points for honours in a hand are a gift for a piece of pure luck but there is more to it than that. A player holding four honours might be tempted to go to almost any lengths to have the hand played in that suit when in fact it might pay him better to play in or against another suit and forego the honours bonus.

In addition to rubber bridge there is duplicate bridge in which several pairs play the same hands. For those who have reached a certain standard this is excellent for spotlighting weaknesses in one's play. As there are no rubbers, points are scored for games. Rubber bridge is generally played for money though the stakes can be quite small. Duplicate bridge is not.

Bridge suffers from a certain mystique which frightens some people. They hear of card sense and fear they might not have it. Actually the only qualities required are common sense and concentration, and card sense comes from playing cards. It is fairly widely believed that women make better players than men at all levels up to the very top where the men take over. The bidding systems or conventions by which players give or request information also frighten people and in earlier days these made up the porters of the older versions describe contract as a game for cheats though of course it is not. In addition to the actual laws there are a number of proprieties which must be observed. Regular partners must not devise their own private bidding system. Only recognised systems may be used and these must be communicated to the opponents. Unorthodox bids may be made but not by prior arrangement with one's partner. There are almost countless conventions and in the very top class players have an imposing list beside them. Beginners will soon learn those used in their own circles.

There are professional bridge teachers and it is also possible (though not easy) to learn from books. Most people though learn at home having a few lessons from friends and then learning by playing. The first thing to learn is how to value a hand and this is done either by allocating points to cards or more effectively by assessing the tricks. Some players assess only honour tricks but as honours take on average, only eight of the 13 tricks this is not really sufficient. The value given to the hand may have to be readjusted on hearing the partner's bids. It is important to bid up to the full value of the combined hands.

There are countless bridge clubs, many quite small and informal and some limiting novices to very small stakes until a certain standard has been reached. Eventually more people will probably learn at school for unlike most card games bridge is encouraged in many schools and the English Bridge Union runs an annual schools tournament.

Bumping Races See Boat Races

Camping.

Camping expresses the townsman's desire to get away from cities and fend for himself in quiet. But some organisation is necessary to provide camping facilities and to maintain high standards. The Camping Club of Great Britain and Ireland has a membership of over 100,000. Its work is twofold: it selects sites suitable for mobile campers and caravanners and establishes and maintains well-equipped permanent camping grounds. A *Sites List* published annually contains details of

CHESS

2 000 camp sites. Members agree to abide by the Club's Code of Campers which stresses the need of the camper to pay full regard to the countryman's way of life and to maintain by country courtesy the goodwill of those among whom he camps. The Club's address is 11 Lower Grosvenor Place London S W 1

Canadian Football

Canadian Football resembles American (qv) but is twelve a side uses only three downs and limits blocking

Canoeing

Canoeing is both a recreation and an organised competitive sport. Beginners should visit Crystal Palace National Sports Centre for the Canoeing Exhibition each February

As a recreation, it can take the form either of simply taking a canoe out and paddling about for a short period or by combining it with camping (qv) of a lengthy and interesting river trip the canoe camper proceeding of course at his own pace and giving as much time as he wishes to sightseeing

As a sport canoeing has Olympic Games status. In Britain it has its headquarters on the Thames at Teddington in Middlesex the governing body being the British Canoe Union 26 Park Crescent London W1N 4DT. There are races for singles and pairs including events for women. There is also one long annual race for pairs that really combines canoeing with camping. The course is from Devizes in Wiltshire to London and the competitors have to negotiate a long series of locks

There are two types of canoe. Canadian canoes, like those used for many years by Red Indians, and kayaks, the very light Eskimo type canoes in which an expert but not a beginner can turn a complete circle into the water and out again without losing his seat in his craft. Both types are catered for in the Olympic Games but most of the canoeing in Britain is in kayaks

Card Games See Bridge Patience Solo Whist Whist.

Chess

Chess greatest of all board games and a game of pure skill has a known history of some 1500 years. Eastern players who originated it reached a high standard but the game's greatest advances were made in Italy in the fifteenth and sixteenth centuries. In the early days the value of the pieces and their moves underwent periodical changes, but the game we know to-day dates from the sixteenth century

The board has 64 squares in eight rows of eight and each player has 16 pieces, one set being white and the other black or red, but always referred to as black. A toss decides possession of white which always starts. The object is the capture of the opponent's King no matter how many pieces are lost in doing so nor how many opposing pieces remain untaken. If the King could be captured on the next move it is in check. It must be released from check (by moving by covering or by capture of the checking piece) otherwise it is checkmate and the game is over. If the King is not in check but cannot move except into check and the player has no other pieces he can move it is stalemate and a draw. Games may also be drawn if neither player has sufficient pieces to force a win

In addition to the King each player has a Queen, two Bishops, two Rooks—sometimes wrongly called Castles—two Knights, and eight Pawns, and all these move in accordance with rigid rules. The following diagram shows the pieces at the start of a game

U9

GAMES AND RECREATIONS

(The initial position as seen by White)

Each line of squares across the board is a rank, and each line up and down the board is a file

The permitted moves are as follows —

The King  can move one square at a time in any direction.

The Queen  can move in accordance with the powers described below or both Bishops and Rooks

The Bishops  move diagonally as many squares as desired.

The Rooks  move straight along the ranks or files as far as desired.

The Knights  move as shown in the following diagram —

(The Knight's Move)

Stationed away from the side of the board and on a black square the Knight illustrated can move to any of the numbered white squares. The move is one square along rank or file in the desired direction and one square diagonally. The

Pawns  move straight forward one square at a time but may move two squares when moved for the first time. They capture by moving one square diagonally forwards. A Pawn reaching the eighth rank may be replaced by any other piece.

Once during a game a player may "Castle" by moving the King two squares towards the Rook, which is placed on the last square passed over by the King. This move cannot be made if either

the King or any of the squares he would pass over are in check. Neither King nor Rook must have moved previously.

Games of chess can be recorded so players can play over great Masters games and record their own games.

Draughts Draughts—called checkers in America—is also played on a chess board. Possibly older even than chess it is much simpler but not devoid of skill.

Each player has twelve pieces or men all alike. Squares of one colour only are used the men starting on the first three rows on the board. The move is one square diagonally forward but a man reaching the eighth row becomes a King and may then move forward or backward. The object is the capture of all the opposing men by jumping over them. If the arrangement of the men permits it more than one man may be captured in a single move. A man which can effect a capture but does not do so is removed from the board or huffed.

Cricket

Cricket traditionally England's national game has a longer history than most team games. There have been attempts to trace its origin in various games played by ancient races and even if some of these derivations are a little far fetched, it certainly developed from very old country games and has been played in a form not so very dissimilar from that of today for over 250 years. The men of Hampshire particularly the village of Hambledon, Surrey and Kent were the real pioneers of the cricket of today.

Cricket is played by two teams of eleven players which bat and field in turn. In the centre of the ground are two wickets 22 yards apart and each consisting of three stumps joined at the top by two bails. Bats have a convex striking surface and the ball must not weigh less than 5½ ounces nor more than 5½ ounces.

There is a batsman at each wicket and their object is the scoring of runs by hitting the ball away and running before it can be returned each time the two batsmen cover the length of the pitch counting as one run. Should the ball be hit beyond the boundary line round the ground it counts four or if it crosses the line without touching the ground six.

The ball is bowled from one wicket to the batsman at the other six balls or in some cases eight which comprise an over being bowled from each end in turn. The object of the fielding side is to get the batsmen out ten dismissals completing the innings as the eleventh man is left without a partner.

A batsman can be dismissed in several ways. If he misses the ball and it hits the wicket or if he plays it on to the wicket he is out, bowled. If he leaves his ground indicated by a line in front of the wicket, misses the ball and has the wicket broken by the wicket keeper he is out stumped. If he hits the wicket with his bat he is out hit wicket. If his hit is caught he is out caught. If when running he fails to reach his ground before the wicket is broken he is out run out. If a ball when bowled would have hit his wicket but hits his leg instead, then subject to certain provisions regarding where the ball actually pitched, he is out leg before wicket. A batsman may also be given out if he handles the ball or obstructs the fielding side but these are rare occurrences.

In addition to runs hit by the batsmen, there are certain extras. If the ball passes the batsman the wicket and goes far enough for the batsmen to run, it is a bye. If however it goes off the batsman's leg it is a leg bye but leg byes cannot be run unless the batsman was definitely attempting a stroke. If it is bowled so wide that the batsman cannot reach it it is a 'wide.' If the bowler comes in front of his wicket before releasing the ball, or if he throws it it is a 'no-ball,' in which case the umpire calls

it as quickly as he can for the batsman can hit such a ball but he cannot be out to it unless he is run out. If he does not score one extra is added.

Of the fielding side one of course is the bowler and another placed behind the batsman's wicket is the wicket keeper. The others will be placed as the bowler and his captain decide for there are far more recognised positions than can be occupied at one time. To gain some idea of these positions imagine a right handed batsman at the wicket his left side towards the bowler. The side of the wicket in front of him nearer to his bat than to his body is the off side, the side behind him, nearer to his body than to his bat the leg side. On the off behind the wicket and close to it are the slips and behind them third man. Farther round but still behind the bat and close to it is gully. Level with the bat is point or if he is some way from the bat deep point. In front of the bat but in front also of the bowler's wicket is cover and extra cover. Roughly level with the bowler's wicket is mid off with behind him long off. Similarly on the leg side where long on is the equivalent of long off, mid on of mid off, mid on of wicket and deep mid wicket of cover and extra cover, square leg and deep square leg of point and deep point, short leg of gully, long leg of third man and leg slip of slip.

First class cricket matches last for three six hour days or longer but there are also two day one day and half day matches. Matches of two days or more are two innings games of one day or half a day one innings. If the side batting first which is decided by a toss that gives the winner the choice of batting or fielding first dismisses the opposing side for a smaller score the victory is by the number of runs by which the smaller score was exceeded. If the side batting second pass the other total the game ends and the victory is by the number of wickets the second side still have standing. In a two innings match should the side batting first gain a first innings lead of a certain size normally 150 runs in a three day match it can require the other side to follow straight on with its second innings the leading team keeping its second innings in reserve to be played if needed. If a batting side has sufficient runs and is anxious to see the other side batting while there is still plenty of time to dismiss it it can declare its innings closed. In this case should the second team score enough runs to win it does in fact win even though it may have lost more wickets than had the declaration side.

Cricket is not a fast moving game and for years views have been expressed to the effect that it must be brightened up if it is not to die out. Periodically small changes in the rules are made but for the most part the game just goes steadily on easily retaining a large following that is satisfied with it as it is and still able when big international matches take place to command a place not only on the sports pages but on the front pages of the Press.

Until May 1968 the game was ruled by the Marylebone Cricket Club but although Lord's is still headquarters, the ruling body is now the Cricket Council composed of the M.C.C., the Test and County Cricket Board and the National Cricket Association (representing all grades of cricket up to first class standard).

Outside England, the development of cricket has been peculiar. Even as near at hand as Scotland and Ireland the game has never aroused much enthusiasm and in Continental Europe where many British games have won great acclaim, cricket has gained a real foothold only in the Netherlands and Denmark. In the United States and Canada it is played but only to a small extent. However in Australia, South Africa, New Zealand, the West Indies, India, and Pakistan, it is extremely popular and the national teams of these countries together with England provide the top-class international sides of the game. They meet regularly in Test Matches a rubber normally being decided in a series of five Tests. See U34.

Cricket is rich in technical terms and expressions which are seen and heard frequently through newspapers, television and radio when a Test series is in progress. Many of these are almost self-explanatory but a few never fail to puzzle less-experienced readers viewers and listeners. Prominent amongst these are three types of ball used by bowlers the yorker the googly and the chinaman.

A yorker is a fast ball that pitches just in the batsman's block hole and often passes under his defensive stroke. The term is believed to have originated in Yorkshire but the only known explanation of it is that attributed to a Yorkshire cricketer who asked why a yorker was so called replied simply "Well what else would you call it?" There is an answer to that for the yorker was originally known as a tice. A googly is an off break or a leg break which is disguised because the bowler has delivered the one with the action of the other. A chinaman is an off break bowled by a left-handed bowler to a right handed batsman. These words also lack an authentic derivation.

Cricket has provided one expression that is now heard in many connections. That is hat-trick which dates back to the days when cricketers wore top hats and any player who took three wickets with three successive balls was presented with a white top hat. Now he is usually given the ball.

Croquet

Croquet originated in France and has been played in Britain for about a century. The governing body the Croquet Association was founded in 1868 with headquarters at Wimbledon. Soon afterwards this also became the headquarters of

STANDARD SETTING

Only those portions indicated by a continuous line need be marked on the court.

The order of making the points is indicated by the arrows.

lawn tennis (qv) and it is probable that the rapid growth of that game was a factor that restricted the development of croquet. Croquet however still retains a following and in addition to championships and tournaments it is widely played on private lawns.

The equipment consists of four balls, coloured blue, black, yellow and red, four mallets, usually marked with the same colours, six hoops and a peg. The playing area is 85 yards by 23 yards but this can be reduced, provided that the proportion remains 5 to 4. The hoops which stand 1 foot out of the ground and the peg are placed as shown in the diagram. Generally two players, taking the blue and black balls oppose two using the yellow and red, but singles can be played, each player using two balls, blue being paired with

black, and yellow with red. Each player completes the circuit of hoops twice, finishing by hitting the peg.

Croquet is a game of skill, and players can earn extra turns in various ways such as hitting another ball with their own or passing through hoops. While making their own circuits players also concentrate on leaving their opponents at a disadvantage. Handicap matches are possible through the giving of extra turns, or bisques. A half bisque is an extra turn in which no hoop may be scored.

Croquet can, perhaps claim some credit for a phrase used in everyday life. Pegging out has the rather sinister meaning of dying or finishing but it is actually the term used for finishing a croquet round by hitting the peg.

Cross country See Athletics

Cruising on Inland Waterways

For those who want a touring holiday in Britain away from crowded roads but who do not want to walk or ride, cruising on inland waterways offers a pleasant and interesting alternative. Facilities are available on a number of canals, rivers and of course the Norfolk Broads, and motor-cruisers can be hired complete with sleeping accommodation, bed linen and cooking utensils. At some places, for example the upper reaches of the Thames, those who prefer to do so can hire cruisers without sleeping accommodation and spend the nights at riverside inns. The Inland Waterways Association exists to keep the waterways open and where possible to re-open others. Particulars of available facilities can be obtained from the Association at 114 Regent's Park Road, London N W 1.

Cycling

As a pleasant recreation, cycling offers a wide range of possibilities. Outings can be for a day or part of a day or they can be tours of any length the rider wishes, with the overnight halts spent in hotels or hostels or camping (qv) which can easily be combined with cycling.

As a competitive sport governed in this country by the British Cycling Federation, 26 Park Crescent, London, W 1, cycling offers a remarkable variety for no other form of racing provides events of so many different types. On the Continent, cycle racing is by far the most popular sport and the leading riders are national heroes. The sport, which caters for both amateurs and professionals also has a large following in Britain where it would soon progress still farther if there were more tracks suitable for big events available.

Cycle races are held on banked tracks rather than motor racing tracks on flat grass tracks, on cinder tracks, on indoor banked board tracks, on roads, and even across country. There are races at all distances from short sprints to road tours divided into daily stages lasting for several weeks. There are massed start races, in which all the competitors start together, races in which competitors are drawn in twos or threes through several rounds up to a final and time trials, in which each rider starts alone. (Road Time Trials Council, 210 Devonshire Hill Lane, London, N 17).

Track races may be straightforward races or time trials or motor paced with the riders behind motor-cycles or tandem-paced or pursuit races with riders or teams of riders starting on opposite sides of or spaced round the track or point to point, with points awarded to the leaders at the end of each lap or courses des primes, with a prize for the leader at the end of each lap, or Madison races for teams of two and occasionally three riding one at a time and relieving each other at will. There are also races for tandems and tri-cycles and the sport includes races on both track and road for women as well as men.

In the cross-country side of cycle racing called cyclo-cross, riders cover a cross-country course of perhaps 10 miles, riding when they can and carrying their machines where riding is impossible. Still another form of cycle racing is roller racing. In this, the cycles are fixed on rollers and do not

move at all the distance the riders pedal being registered on large dials. There is also cycle speedway a sport practised only by youths. Events take the form of team matches generally on rough cinder tracks constructed on waste ground with pairs of riders opposing rival pairs in a series of races and points awarded to the leaders in each race. Corners have to be skidded round as they sometimes are in ordinary grass track cycle racing. Very different but still competitive in a way is a form of event that provides a link between the sporting side of cycling and the more purely recreational side the reliability trial or attempt to achieve a fixed standard.

Cycling also has its team game in bicycle polo a hard game requiring a high level of cycling skill and considerable nerve and controlled by the Bicycle Polo Association of Great Britain. The game is divided into six 15 minute chukkas with five players and one substitute on each side. International matches are played and there are national and local leagues.

There is also an organisation that caters especially for the distance tourist in the Cyclists Touring Club which keeps a check on premises offering accommodation to cycle tourists and provides a sign for use on approved accommodation. The address of the CTC national headquarters is Cotterell House 69 Meadow Godalming Surrey. The office for travel facilities is CTC Travel Ltd 13 Spring Street Paddington London W2.

Darts

Originally just a casual amusement confined almost entirely to public houses the game of darts is now one of Britain's most popular pastimes. Public houses still provide facilities for it but to day clubs canteens factories offices and private houses also have their boards and there are numerous team and individual competitions including a National Championship. The prizes rival those of any other game for value matches are widely reported and the attendance for the bigger contests is limited only by the size of the hall. This enthusiasm is not misplaced for the game is a test of skill and luck plays little part in it. The governing body is the National Darts Association of Great Britain.

The standard circular board has a diameter of 18 inches and is divided into segments numbered from 1 to 20 but not consecutively. In addition there are two rings each $\frac{1}{4}$ inch wide that go right round the board and through each segment. These are the double ring at the extremity of the board and the treble ring near the centre of the board darts in these rings counting double or treble the value of the segment. In the centre of the board there are two small rings the bull or dossier counting 50 and the outer counting 25. The bull is 5 feet 8 inches from the ground and the wooden or metal feathered darts are thrown from a line called the hockey usually 9 feet away.

Matches may be singles doubles or between teams of four or eight players. Games are for a certain number of points usually 101 201 301 501 801 or 1001 the lower totals being used for individual and the higher for team contests and matches are generally the best two out of three games or legs. Conditions for matches vary but normally stipulate either straight start and finish on a double or start and finish on a double. In the first case players score from the start but in the second they do not score until one double has been registered. In both cases they must finish on a double and they must finish with the exact number they require. Scores are counted downwards players being told how many they need, rather than how many they have scored.

In addition to the straightforward game there are many darts variations. In one Round the clock a player has to throw one dart into each segment from 1 to either 20 or the bull his turn continuing until he throws three darts unsuccessfully. In Shanghai players start with a complete throw of three darts at number 1 and continue with a throw at every number up to 9 but players who fail to score at number 5 drop out

In cricket one player bats throwing normally and counting everything over 40 while the other bowls throwing only at the bull and counting one wicket for every outer and two for every bull five wickets ending his opponent's innings. In a darts version of shove ha penny players have to get three darts in each segment from 1 to 9 and three in the centre. In Fives players score only if their total is divisible by five.

Diving See Swimming

Dominoes

Dominoes are similar in many ways to cards in that many games can be played with them with varying degrees of skill. Players play (or pose or down) in turn from hands. The game was introduced in Europe by way of Italy in the 18th century though the actual games as they are played today and also the scoring methods are of French origin.

The domino itself (called a *card* or *stone*) is oblong with its face divided by a centre line and marked in each half by indented dots. A set normally consists of 28 pieces respectively marked 6-6 (double six) 6-5 6-4 6-3 6-2 6-1 6-0 5-5 5-4 5-3 5-2 5-1 5-0 4-4 4-3 4-2 4-1 4-0 3-3 3-2 3-1 3-0 2-2 2-1 2-0 1-1 1-0 0-0 (double blank). (There are special sets for games consisting of 55 pieces running up to 9-9 and 85 pieces running as high as 12-12).

In the common form of the game using 28 pieces the dominoes are laid face downwards on the table each player taking seven the rest being left as a reserve. A player stands his hand so that the faces of his pieces are visible to him but not to his opponents. The idea of the game is to match the number on one domino half to that of the free half of a piece already played on the table. Pieces are laid end to end but double pieces are laid transversely and allow the player an extra turn. The winner is the one who plays all his pieces.

Variations include playing a piece that is not the same as the one to which it is fitted, but that with it adds up to seven or one that will make the two ends of the line add up five or a multiple of five or three or a multiple of three. Another variation makes the double blank and any piece on which the two halves add up to seven *matadors*. These are the equivalent of the card player's wild cards and may be played at any time.

In some games a player who cannot play simply misses the turn while in others he may draw from the reserve having of course to retain the domino in his hand if he still cannot play.

Games are for two three four or more players and in some of those for four players two play together against the other two each player trying to block his opponents but to assist his partner.

As with cards solitary players can play patience and this is a good way for a beginner to learn how to play a hand. The player picks five dominoes from a shuffled set starts with any piece he chooses and then continues to play in the normal way. When he cannot play he draws enough pieces from the reserve to make his hand up to five and carries on continuing until either he can play out or cannot play at all from the pieces left.

In the more skilful games as in the more skilful games of cards a good memory is an asset as it is essential to remember which player played which piece.

Drama

Few countries can boast so eager an interest in amateur drama as Britain and it is estimated that there are some 20 000 groups in the British Isles with half a million membership. The cardinal influence in this enormous movement is the British Drama League to which some 3 500 groups belong besides over 1 000 private individuals.

The league's influence on drama is exercised in two ways. Its members have the use of the library which possesses the largest collection of plays and books on the theatre in Great Britain and of its information services which give help and advice on every conceivable dramatic topic. They can of course hire sets of plays (one copy for each character up to twelve). Then there are the league's training schemes. Courses in production, acting and décor take place in London all the year round and there are summer courses in the country. The address of B D L is 9-10 Fitzroy Square London W 1.

It was not until the great International Theatre Exhibition at the Victoria and Albert Museum in 1922 that the English public became fully aware of the new man who had arrived in the theatre—the producer or director as the Americans call him. It is the producer who decides how the play is to be produced and sets his signature upon it very much like the conductor of an orchestra. In this task he unites the work of the author, actors, designers and craftsmen of various kinds. The technical side of staging a play is a fascinating one involving problems of the frame work (the stage sight lines auditorium) curtain settings lighting skylights the construction of scenery designing the scenery and the making of scale plans and models painting the scenery lighting and so on.

Television offers new opportunities for the playwrighting aspirant with its need for new methods. In the theatre the playwright and actor must make all things plain to distant members of an audience—whereas the television actor's slightest change of expression is clear to the person sitting within a couple of yards of him. A wink a nod a shrug on the television screen suffice for the implications which would be lost in the theatre. The gearing so to speak between text and meaning is different. A new field opens therefore for the writer for television drama.

Draughts See Chess.

Eton Fives See Fives.

Fencing

Fencing can claim a longer history than most sports for it is the modern equivalent of duelling. In mediæval tournaments mounted knights fought with lances, and in addition to actual fights to the death they also met with special, less lethal lances purely for sport. Later duels were fought dismounted, and with different weapons. In Elizabethan days duellists used a sword, for attacking in the right hand and a dagger for defence in the left. Later still, the dagger was discarded and duels were fought as are fencing bouts to day with a sword only.

Duelling declined in Britain during the Regency period when it became fashionable for gentlemen to learn to fight with their fists but they continued to learn swordsmanship and to fence with the practice weapon, the foil. Eventually duelling became illegal almost throughout the world, but swordsmen of other countries similarly continued to fence with the foil. Even before Britain took to fist fighting, most of the advances in fencing technique had been made in France and Italy and the fencers of these and other Continental countries are still the best in the world, countries like Britain and the United States relying largely on fencers of Continental European descent.

Nowadays widespread class tuition in fencing has opened the sport to anyone.

Modern fencing includes contests with three weapons the foil, which is the only one used by women, the épée the real duelling sword and the sabre which cuts as well as thrusts. These weapons have buttons on the points, but fencers wear a special glove a padded jacket and a mask. Fencing requires grace of movement lightness of foot agility strength of wrist and forearm quick mental reactions, and good eyesight and it will do much to develop these qualities including the eyesight. As masks are

worn it is perfectly practicable to fence wearing glasses.

The governing body of the sport is the Amateur Fencing Association 83 Perham Road London W 14.

Figure Skating See Skating

Fives

There are two games of Fives. Eton Fives and Rugby Fives. They are court games using walls but an Eton Fives court has the addition of a buttress or pepper jutting out from one side wall. The striking implement is the gloved hand. Eton Fives is a doubles game but both singles and doubles are played in Rugby Fives.

Folk Song and Dance

Whether or not you play sang or dance your self you can enjoy the heritage of English folk music song and dance. To enable you to enjoy it to the full the story of Cecil Sharp House will be useful. Cecil Sharp went out to collect the folk songs of England in the fields and cottages in almshouses and by the roadside. He systematically combed some counties like Somerset. Cecil Sharp and Vaughan Williams joined the English Song Society which had had Elgar and Parry among its first members. Sharp went on to note down folk dances and to publish details of the steps and figures. In course of time he founded the English Folk Dance Society to restore their traditional dances to the people of England. The two Societies amalgamated in 1932 and today Cecil Sharp House (2 Regents Park Road London N W 1) is the home of the English Folk Dance and Song Society with over 12 000 members.

Scottish Dancing and singing are the primary objectives of special holidays by the Holiday Fellowship at Scottish centres and Old Time Dancing is enjoyed at an English Centre. Folk dancing is also the feature of special holidays by the Cooperative Holidays Association.

Football. See American Football Association Football Australian Rules Football Canadian Football Gaelic Football Public-School Football Rugby Football.

Gaelic Football.

Gaelic Football is seldom played by anyone who is not Irish, but it is frequently played outside Ireland for Irishmen have taken it with them to Britain, the United States Australia and South Africa.

Played fifteen a-side it is a blend of Association and Rugby football (qv) the goals having the uprights, cross-bar and net exactly as in Association, but having the uprights extended above the cross-bar as in Rugby. If the ball goes under the cross-bar it is a goal and if it goes over it is a point a goal equalling three points. The ball is round, and it may be kicked or caught but not thrown forward, nor carried though it may be dribbled by bouncing it. In its essentials, it is probably simpler than most other forms of football, but it is fast and involves frequent hard bodily contact. Substitutes are permitted in case of injury.

Gaelic football joins with hurling (qv) in coming under the old-established Gaelic Athletic Association.

Gliding

The first serious efforts to develop gliding which is flying in engineless aircraft or sailplanes making use of natural air currents, took place in Germany in 1919 and were successful enough to lead to experiments in France and England, where it arrived in 1922. At that time however, it failed to gain much support and the real history of gliding in Britain dates from a second attempt to encourage it in 1929. Little more than ten years later gliding had advanced sufficiently to be a real factor in the second World War.

Skilful use of up-currents enables the glider pilot to stay up and if the air is rising faster than the glider is sinking the glider will climb

Glders can now reach altitudes of over 40 000 feet stay in the air for over 50 hours and carry out flights of hundreds of miles It is an exhilarating sport and certificates for various grades of skill and experience are awarded by the British Gliding Association 75 Victoria Street London S W 1 to which some 70 clubs are affiliated

Golf

Golf a game of great antiquity originated in Scotland and is now widely popular in many countries It consists of using a set of clubs with which to play a small white ball over a cross country course of eighteen holes Each hole will be several hundred yards long and will have its fixed starting point and its finish with an actual hole in the ground the object being to complete the course which will be several miles long in as few strokes as possible

The playing of each hole falls into three sections driving approaching and putting The starting point will be a flat piece of ground on which the player will tee up his ball on a small rubber peg or tee which he will carry round with him He will then hit the ball towards the hole concentrating on achieving distance From the tee to near the hole is the fairway which will consist of fairly smooth ground not entirely devoid of natural obstacles and probably containing some sand traps or bunkers On each side of the fairway is the rough which may consist of long grass shrubs woods or even roads The player will continue to play his ball towards the hole concentrating now chiefly on direction On the fairway or off it he should always play his ball where it lies but should it be quite unplayable or even lost he may drop it or a new one and pay a stroke penalty for the privilege The actual hole will be on the green a rough circle of exceptionally well tended grass and once on it the player will cover the last few yards by the more delicate art of putting

There are many different types of club players being limited to fourteen The shafts are generally steel the striking surfaces being iron or, in the case of drivers wood The different irons have numbers but golf clubs used to have special names often descriptive of their functions for instance lofties cleek masher mublick and even blaster Originally most golf courses were by the sea and these were called links a term now loosely applied to any course

There are two actual methods of competitive play match play and medal play Match play is by holes a player completing any hole in fewer strokes than his opponent winning that hole Once a player leads by more holes than there are still to play the game finishes the victory being by X and Y where X is the number of holes he is up and Y the lesser number of unplayed holes When a player leads by the same number of holes as there are still to play he is said to be dormy so many Opponents level after eighteen holes proceed to the first hole and play on until one is one hole up when he is said to have won at the 19th 20th or whatever it may be Some important match play events are over 36 holes or two complete rounds Medal play is simply stroke play the result depending on the number of strokes needed to complete the course This demands a higher level of consistency for one bad spell can ruin the total whereas in match play it may cost only one hole In play after the initial drive the player farthest from the hole normally plays before his opponent

In match play championships and tournaments players are drawn against each other the winners going on to the next round, and so on up to the final In medal play events players go round in pairs but each is of course playing against the whole field Team matches consist of singles and foursomes, in which the partners play shots in turn Other less formal forms of golf are four-ball foursomes in which each player plays his own ball best-ball foursomes, in which both partners drive, but thereafter play in turn only

at the most successfully driven ball and three some, in which each player plays for himself against the others During a match a player must not receive advice from anyone except his caddy if he has one the caddy being an attendant who makes a profession of carrying golfers clubs round

Every course has its bogey and par figures these being scores with par representing the higher standard that a first-class player might achieve for the course By assessing a member's own scores against these figures clubs can allocate a handicap which indicates the player's standard There are many minor competitions in which golfers play not on level terms but from their handicaps which also serve as a perpetual incentive to players to improve their game and therefore their handicaps The possession of a handicap also makes it easier for players to arrange even matches with strangers Handicaps are subject to alteration as a player's standard changes and such alterations may be in either direction The operation of the handicap in play takes the form of strokes deducted from the actual score at certain holes in accordance with the arrangements in force at any particular club

Golf offers a tremendous number of competitions of all standards as well as championships and team matches Probably the four most important individual championships are the British Open the British Amateur the American Open and the American Amateur These are long established but the two major international team events are quite new They are the World Cup open to teams of two professionals from any country and the Eisenhower Cup for teams of four amateurs the three best scores counting from any country Other much older international team events include the Ryder Walker and Curtis Cups which are contests between Britain and the United States for professionals amateurs and women respectively though it is interesting to note that the actual inscription on the Curtis Cup indicates that this trophy is open to women golfers of any country

Golf is ruled by the Royal and Ancient Club of St Andrews Scotland which is recognised all over the world as the game's headquarters There was an unusual illustration of this widespread recognition when the Eisenhower Cup competition was instituted by the United States in 1958 for at the special request of the American organisers the first meeting took place not in the United States but at St Andrews The Royal and Ancient Club makes the rules of golf but these are generally supplemented by local rules in force at particular clubs

The popular expression rub of the green used to describe an unexpected and unavoidable mischance comes from golf where it is used when a putt fails to take the expected line because of a slight flaw in the normally perfect turf of the green

Gymnastics

Gymnastics is a system of exercising with apparatus and also a competitive sport the chief items of apparatus used being the horizontal bar the parallel bars rings ropes ladders and the vaulting horse The horizontal bar the parallel bars and the rings can all be used for similar exercises some being fast swings and others slow movements requiring considerable strength Strength and swinging also come into ladder exercises and the rope which can be climbed in several different ways, is a simple form of apparatus that demands and will develop strength The horse can be used for a variety of vaults in either the lengthways or sideways position, and still others are possible when pommels are fitted to it In addition to those who specialise in gymnastics many sportsmen of various kinds regularly attend gymnastic classes as part of their training for their own particular activities

The trampoline which is something like a large and very springy mattress and which has long been used by circus and stage acrobats, has now been accepted as a piece of gymnastic apparatus gymnasts divers and other sportsmen use it in

training it is also used in the Services in the training of commandos and parachutists. There are trampoline competitions and championships in which gymnasts perform many of the acrobatic feats normally performed on the floor.

Hockey

Hockey originated about three quarters of a century ago as a game confined to Britain but with rules that varied in each of the home countries. However in 1900 England, Ireland, and Wales combined to form the International Hockey Board with a view to formulating rules that would apply wherever the game was played and two years later Scotland joined the alliance. The game was also taken up with terrific enthusiasm in India and Indian players became and remain the best players in the world. Their enthusiasm extended to what is now Pakistan so

In play the ball must be propelled only by the stick, and it must not be stopped with any part of the body except the hand in which case it must only be stopped and not caught or knocked forward. These prohibitions however do not apply to goalkeepers who may stop the ball with any part of their body and also kick it when in their circle. No part of a player's stick must be raised above the shoulder either at the beginning or end of a stroke or to stop the ball. Hitting the ball in the air and scooping it are allowed but deliberate undercutting is not and umpires can penalise any hit which they judge to be dangerous. Interfering with an opponent's stick running between an opponent and the ball and charging or other bodily contact are not allowed. Players must not tackle from the left unless they can play the ball without touching the opponent or his stick.

A player is offside if there are fewer than three opponents between him and the goal line unless he is in his own half or unless a team mate playing the ball is nearer to the goal line than he is. A player who is offside is put onside if an opponent plays the ball but not if the ball merely touches or glances off the opponent. Players who are offside are not penalised if they do not interfere with the play.

GROUND—100 yards by 55 to 60 yards. OPENING OF GOAL—7 feet by 12 feet.
Diagram of Ground as marked out for Hockey

the division that brought that country into existence also added one more to the list of hockey playing countries, and without noticeably weakening India's own national team.

Hockey is now played in many other countries but for some time it made little progress on the Continent. Eventually though it was tried, liked and adopted in a number of European countries and one of these the Netherlands has now established a right to a place alongside India, Pakistan and Britain as the game's top layer. Hockey has and has long had Olympic Games status.

Hockey is played eleven a side on a pitch marked out as in the accompanying diagram, the normal positions of the players being a goalkeeper, two full backs, three half backs and five forwards exactly as in Association football (q.v.). The white ball can be either sewn, as is a cricket ball, or seamless and it must weigh from 5½ to 6½ ounces. Sticks must weigh from 12 to 28 ounces, and have a handle that can be passed through a ring with an inside diameter of 2 inches. They have a striking surface on the left side only left handed sticks not being permitted. A game consists of two 35 minute halves unless the captains have agreed on a shorter period.

The game is started, and restarted after half time and after a goal by a bully at the centre of the ground. The players bullying stand facing the side line each with his own goal on his right. Each taps the ground between the ball and his own goal and his opponent's stick over the ball three times alternately after which one of them must play the ball. At any bully all the other players must be 5 yards from the ball and between it and their own goal.

If the ball crosses the side line it is rolled in by a player of the side that did not put it out. This player must have his hands feet and stick outside the field of play and he must not play the ball again until someone else has done so. All the other players must have their feet and sticks inside the 7 yard line until the ball leaves the roller's hand.

If the ball is sent across the goal line wide of the goal by an attacker or unintentionally by a defender who is more than 25 yards from the goal line, the restart is by a bully on the 25-yard line. If it is hit behind unintentionally by a defender who is within 25 yards of the goal line a corner is awarded to the attacking side. If it is hit behind intentionally by a defender from any part of the ground a short or penalty corner is awarded to the attacking side. A corner is a hit from a point on either the goal line or the side-line within 3 yards of the corner flag while a short corner is a hit from a point on the goal line 10 yards from the nearer goal post. At a corner all the defenders must be behind the goal line and all the attackers outside the circle. When the corner hit comes into the circle attackers are not allowed to take a first time shot but must first stop the ball or slow it down. At no time during the game can a goal be scored unless it is hit from inside the circle.

Penalties for infringements outside the circle are generally free hits. Penalties for infringements inside the circle by defenders are short corners, unless they have been deliberately committed to prevent a goal or have in fact, prevented a goal in which cases a penalty bully is awarded. In extreme cases, both short corners and penalty bullies can be awarded for offences anywhere behind the 25 yard line.

In 1963 the penalty stroke was introduced. This replaced the penalty bully, a duel between the offender and one opponent, with all the other players beyond the 25 yard line that started with a bully 5 yards from the centre of the goal and continued until either a goal was scored or the ball was hit behind the attacker or out of the circle by the defender. If it was hit behind by the defender the bully was restarted. This was a novel feature but a not altogether satisfactory one as the duel was sometimes protracted. The penalty stroke if less spectacular is also less complicated. A game is controlled by two umpires each of whom takes one half of the field and one complete side line. Substitutes are not permitted in hockey.

Hockey is entirely an amateur game. Until recently most club matches were friendlies but the new London League of top clubs seems to be flourishing, plus some rather specialised cup competitions. There are however a great many representative games from county matches to internationals.

A major feature of the hockey season which normally lasts from October until March (although summer games usually played in the evening are becoming increasingly popular) is the end of season Easter Hockey Festival. There are several festivals most of them taking place at seaside resorts. Teams go from many different areas including the Continent and play three or four matches in four days against opponents whom they would not normally meet. Six a side tournaments also take place occasionally during the season.

Hurling

Hurling which might loosely be called the Irish brand of hockey (*q v*) is played fifteen a side and has been described as the fastest game using a ball in the world. The ball called the sliotar and the sticks called hurleys bear some resemblance to hockey's ball and sticks but nothing like hockey's sticks rule applies. The sliotar may be hit at any height and with either side of the hurley and it may be kicked or caught though it must not be carried more than three steps nor picked up off the ground. There is no offside apart from the fact that attackers must not enter the parallelogram marked out near the goal ahead of the sliotar. The goals have uprights that are extended above the cross bar and scoring is by goals under the bar and points over the bar, a goal equaling three points. There is a good deal of bodily contact and substitutes are permitted for injured players.

Hurling rarely played by anyone who is not Irish but often played by Irishmen outside Ireland is of great antiquity and the English authorities in Ireland first tried to suppress it six hundred years ago. It was kept alive however and it is very much alive to day. To Irishmen hurling and Gaelic football (*q v*) are symbols of nationalism and patriotism. They are governed by the Gaelic Athletic Association, which has a rule that states: "Any member who plays or encourages Rugby Association Football, Hockey or Cricket by that very fact incurs an immediate suspension from membership of the Association."

A form of hurling with slightly different rules called shinty is still preserved in another Celtic country Scotland.

Knur and Spell. See Old English Games and Customs.

Korfball.

Korfball is a team game with several unique features, the most striking being that it is a mixed

game a team consisting of twelve players—six men and six women. The game resembles basketball (*q v*) in some ways the goals which are 11½ feet high and the scoring of goals being similar. It can be played on any firm surface the pitch measuring 800 feet by 183 feet though a smaller pitch can be used provided that length and width are reduced in proportion. The pitch is divided into three sections and players do not move from one sector to another during actual play. They must however change to another zone after every two goals. This encourages all round attacking and defensive ability and ensures that even in a one sided match every player gets a fair share of the game. Four players from each team play in each section and players always mark opponents of their own sex. Players must not run with the ball which is advanced purely by passing. There is no tackling and the ball can only pass from one team to the other by interception. Players may not score if there is an opponent within arm's length. A game lasts for 90 minutes divided into two halves.

Korfball originated in the Netherlands where it was first played in 1902. It spread to Belgium in 1927 and reached England in 1947. There is an International Board on which the Netherlands, Belgium and England are represented. International inter club matches are a regular feature of the game. Though really a winter game korfball is actually played all the year round the international games between clubs from the three korfball countries taking place during the summer.

Lacrosse

Lacrosse which originated from a game played by the Red Indians was introduced into England from Canada in 1867 and has been played here ever since.

The object is the propelling of a rubber ball through goals 6 feet wide and 6 feet high with a wooden crosse not more than a foot wide at its widest point when there is a mesh of strings. The goals are from 90 to 110 yards apart but play can take place behind them for there are no boundaries to the pitch except the natural borders of the field unless the captains have agreed otherwise. The only lines required are the centre circle the goal lines and the goal creases.

In England teams consist of twelve players but in Canada and the United States the number was reduced to ten some years ago. Players line up right down the field instead of only in their own half and there is no offside except that no attacker may enter the goal crease before the ball. Should a player leave the field through injury his opponents must also withdraw a man.

A game consists of four 20 minute periods but the captains can agree to vary this either to two 45 minute halves or otherwise. The game is started or restarted after a stoppage by one player from each side facing by placing the ball on the ground between the backs of the two crossees and then drawing them apart after which the ball is in play. It can then be advanced by running with it on the crosse throwing it from the crosse or kicking it though no goal except an own goal can be scored by a kick. Only the goalkeeper who can deflect the ball with his hand, but not catch or throw it may handle the ball. Players can shoulder opponents when trying to get the ball off the ground and body check them by simply standing in front of them to impede them. A player can also check an opponent's crosse with his own crosse if the opponent has the ball. A foul is penalised by giving the non offending player a free position, which means that he is given the ball and the game is then restarted.

Lacrosse demands speed and stamina and a high level of skill demands practice but it is basically a simple game. Seven a side lacrosse is suitable for school practice—designed to be played in a gymnasium or on a netball court.

It is interesting to note that Lacrosse which can be one of the roughest of all games has been made a suitable game for women by very simple measures such as the elimination of the body

check— and that there are now more women playing than there are men

Land and Sand Yachting See Yachting

Lawn Tennis

Originally called Sphairistike—or Sticky by those who disliked it—Lawn Tennis was invented in the seventies of the last century as a simplified outdoor version of real tennis (q v) using a net but no walls. It is now far more widely played than the parent game being popular almost all over the world. As its name implies, it was originally intended to be played on grass, but it is now also played on hard courts of various surfaces and indoors on wood.

The court is as shown in the accompanying diagram the outer long boundary lines being the limitations for doubles and those parallel to them being the boundaries for singles. Both server and receiver score four points making a game six games won a set and two out of three

NET—Height 3 ft 6 in. at posts, 4 ft at centre
Diagram of Ground as marked out for Lawn Tennis

or three out of five sets won a match. Game points are scored 15, 30, 40, and Game. The system of advantage games and sets is used. This means that if 40 all—called deuce—as reached a player must gain a clear lead of two points to win the game the winner of the first point after deuce being said to have the advantage. If the games reach 5 all, the set continues until one player has a clear lead of two games though the tie break system—the best of the next 12 points—may soon be more widely adopted.

When the game began there was considerable discussion before this scoring which is taken from tennis was given preference over the straight forward one two-three system of rackets (q v). Much more recently experiments have been made with the equally straightforward system of table tennis (q v) but the tennis system survived these and remains in force.

Service is almost invariably overhand, and the receiver plays the service after one bounce. Thereafter strokes may be ground strokes, played after one bounce or volleys, played before any bounce. In doubles either partner may play the ball but each must serve in turn.

In addition to being played by thousands of people lawn tennis attracts large crowds of spectators. The big annual tournaments, such as Wimbledon, Forest Hills and Paris are amongst the major sporting events of the year as are the Davis Cup competition, open to teams of men from every country in the world and the Wightman Cup women's contest between Britain and the United States. Since April 1968 the I.T.A.'s new rule 30 has made it possible for amateurs and professionals to compete against one another in tournaments in this country.

Marbles. See Old English Games and Customs.

Modern Pentathlon.

Imagine a king's messenger riding with an important dispatch and being hotly pursued. His horse is shot and he has to engage his pursuers first with his revolver and then with the sword. Eventually he breaks away swims a river and finishes his journey on foot and running.

That is the plot on which is based one of the most interesting exciting and testing of all sporting events the modern pentathlon. Often wrongly thought to be a part of Athletics the Pentathlon is a separate sport but one that actually consists of five different sports the five activities in fact of the king's messenger in the story riding, revolver shooting, fencing, swimming and running. True the pentathlon competitor does not have to carry them out one after the other but he does have to take part in them in that order one on each of five successive days both riding and running being across country the riding on a horse strange to him.

The pentathlon first appeared in the Olympic Games of 1912, but in recent years, it has become so popular that, in addition to the Olympic event every four years, there are now annual world championships as well as national championships in many countries including Britain. The event was originally designed as one suitable for Army officers, and though present day Army training is rather different most pentathlon competitors are still servicemen, though they are not all officers. However a civilian has won the Olympic event and in Britain, the Army authorities are willing to provide training facilities for civilian competitors who show signs of reaching a high standard. Many people believe that the keys to success in the modern pentathlon are swimming and running and that competitors who are good at them can be taught the riding, shooting and fencing without too much difficulty.

Mountaineering

Among famous peaks, Mont Blanc was first conquered in 1786 the Jungfrau in 1811 and the Wetterhorn in 1854. By then mountaineering was becoming organised and there were systematic assaults on the Alps in Norway the Caucasus and Corsica in the Rockies and the Andes in Japan, New Zealand, and Kenya and, of course in the Himalayas, where over thirty years passed between the first assault on Everest and its conquest in 1953. There are still unexplored peaks in the Himalayas but it is not only first ascents that interest the mountaineer, he can find exciting climbing in many parts of the world.

The way to master mountaineering is to accompany and watch experts. Perfect physical and nervous fitness is essential, as is a detailed knowledge of snow, ice, avalanches, glaciers, crevasses and cornices and of the different

techniques of ascending descending and traversing. Also to be learned is step cutting which is hard manual labour carried out under difficult conditions that may make perfect workmanship literally a matter of life or death. Clothing properly nailed boots ropes ice axes knives maps compasses medical supplies must be of the best and yet at the same time light.

Mountaineering is generally taken to mean snow and ice climbing but allied to it is rock climbing which demands the same perfect physical and nervous condition and in place of knowledge of snow and ice knowledge of several very different kinds of rock. Ascending descending and traversing all apply and so do ropes and the rock climber should in fact be something of a knot expert. Light rope soled shoes replace the mountaineer's nailed boots.

The Youth Hostels Association runs training schools for climbers at all stages in Britain and abroad and also runs evening classes on rock climbing in conjunction with education authorities. The Holiday Fellowship organises climbing tours in the Highlands of Scotland climbing many well known mountains. In Scotland useful addresses are the Scottish Mountaineering Club 406 Sauchiehall Street Glasgow C2 and the Junior Mountaineering Club 28 Croftmont Avenue Croftfoot Glasgow S4. At the White Hall Centre for Outdoor Pursuits Manchester Road near Buxton the Derbyshire County Council hold courses for those between 18 and 20 plus on hillcraft rock climbing camping skiing and canoeing. The Outward Bound Trust 123 Victoria Street London SW1 runs schools in Wales and the Lake District to train boys—with a few courses for girls—how to face hazards and hardships of all kinds on mountains and sea.

Courses in advanced mountaineering up to mountaineering instructors certificates and other outdoor activities are run at Plas Brenin National Mountaineering Centre in Snowdonia.

The British Mountaineering Council and the C.P.R. issue a free leaflet *The Mountain Code* from 26 Park Crescent London W1N 4AJ.

Music

One of the most novel changes of the last generation or so has been the widespread diffusion of music not only in this country but all over the world. Twenty or thirty years ago it might have been necessary to travel a long way to hear the performance of a classical musical work and the opportunity of doing so was only occasional. We can now have a constant flow of such music from wireless and record player. Several things follow from this change. Leisure has been transformed by high fidelity and the long playing record. People listen more easily and frequently than they read and it is music rather than literature which is at the centre of culture. Access to good music does not depend upon training and application to the same extent as access to good literature. It is easier for the tired person to enjoy music than a serious book. Where the library shelves used to stand says a commentator there are now the record albums row upon proud and esoteric row. The listener may well be submerged by the easy flow of music of vastly different kinds but there is an opportunity for the discerning listener to compare and to select from the music of the different centuries to study the difference between the classical and romantic masters the emergence of modern orchestration choral music chamber music opera and oratorio. We may go on to study other aspects—the study of the personality of the composers the relation between their work and the problems of the times knowledge of the different instruments and how to enjoy reading a musical score. By this means the listener can combine refreshment of spirit with the delights of exercising skills of various kinds.

All through the summer all over the country there are opportunities for music lovers whether active musicians or not to spend a holiday together and pursue some aspect of music. The leader will probably be surprised to learn that there are nearly one hundred such summer schools each year some for the week end others for a week or fortnight. The Rural Music Schools

Association at Hitchin Herts would help enquirers for particulars. A glance at the annual list shows how wide are the subjects offered madrigal and other singing recorder playing orchestral and chamber music Russian music 18th century music discussion for wind teachers the making of musical instruments. These summer schools are in addition to the Music Festivals held at Edinburgh Bath Cheltenham and other places not forgetting the Three Choirs Festival in the West (British Federation of Music Festivals 106 Gloucester Place London W1). Details of the various continental festivals can be obtained from the European Association of Music Festivals 123 rue de Lausanne Geneva or 82 Beauchamp Place London SW8.

Your local public library probably has a music library. The National Operatic and Dramatic Association 1 Crestfield Street London WC1 has a library of musical scores and dramatic works. The National Federation of Music Societies publishes a catalogue with practical details of some 500 choral works and assists music societies by advice information and in other ways. Its address is 4 St James's Square London WC1. The Workers Music Association provides opportunities for developing musical instincts and tastes believing that genuine art moves people to work for the betterment of society. It organises classes lectures and week end and summer schools and offers correspondence courses in Harmony Counterpoint and Orchestration. Its address is 17 Bishops Bridge Road London W2.

Many local authorities have record departments in their local libraries. The Central Gramophone Library (38 Russell Square London WC1) has a circulating library of records which are available to adult education lecturers music and gramophone societies and to hospitals and prisons. Those interested in forming a gramophone society should get into touch with the National Federation of Gramophone Societies. The British Institute of Recorded Sound 38 Russell Square London WC1 contains the national archives of gramophone records and other sound recordings and is the national centre for information and documents.

Natural History and Field Studies

There are nine field centres in England and Wales at

Juniper Hall Dorking Surrey
Flaxford Mill East Bergholt near Colchester Essex
Malham Tarn near Settle Yorkshire
Dale Fort Haverfordwest Pembrokeshire (including Skokholm Bird Sanctuary)
Preston Montford near Shrewsbury Shropshire
Slapton Ley Slapton Kingsbridge Devon shire
Orrelton near Pembroke S Wales
Nettlecombe Court Williton Taunton Somerset
Rhyd y Creua Betws y Coed Caernarvon shire

The nine centres have been set up by the Field Studies Council in localities selected for their ecological features and for their geological geographical archaeological and artistic interest. Working facilities and expert guidance are available at the Field Centres to all who have a serious interest in the countryside—whether as amateur naturalists or as students or as research workers. They are not reserved for the academic student only. The Council want to encourage and help the beginner and the ordinary person who has an interest in some branch of natural history and wishes to learn of this or allied subjects. The Centres are staffed and suitably equipped to provide residential accommodation and working facilities for numbers ranging up to about sixty persons. Thus field workers enjoy the skilled guidance of the staff local contacts and information bench space tools maps and records with something of the intellectual and social life of a small residential college. There are special courses for amateurs and some of these are less formal than the word 'course' suggests. The subjects vary widely

including bird study, land structure and scenery and outdoor painting and sketching.

Juniper Hall, amidst the beautiful chalk hills of the North Downs, is well situated for almost every kind of field study. Flatford Mill is at the head of the Stour estuary, in the countryside of Constable and Gunborough. The Stour with its tributary streams, its mill pools and cattle ponds and dykes provides excellent scope for water biology. Millham Tarn Centre is on the shore of the tarn on the limestone uplands at the head of Airedale in the Yorkshire Pennines. Here is the rich flora of well drained pastures, screes and limestone. The tarn itself supports an abundant fauna of invertebrates and fish. Dale Fort at the tip of a narrow peninsula guards the approach to Milford Haven. The flowers on the cliffs in May and June are the envy of the rock gardener. The opportunities for the marine biologist are unsurpassed. But there is no specialisation to the exclusion of any of the many subjects that can advantageously be studied. The Bird Observatory on Skokholm island is a part of Dale Fort Field Centre and here work on birds has pride of place. Guillemots and razorbills breed on the rocks and puffins and shearwaters burrow in the edges of the plateau. Preston Montford lies on the banks of the Severn four miles west of Shrewsbury where geological formations are displayed conveniently for study. In the North Shropshire plain is scope for the study too long neglected of the ecology of ordinary English farming country that man has influenced for more than 2,000 years. There are numerous localities of archaeological interest including the Roman town of Viroconium. At Slapton Ley the 300 acres of Slapton Nature Reserve offer ample scope for interest in most branches of Natural History. The Ley is separated from the sea by a shingle bank. There are moorland and bog, slate and limestone cliffs, lake shores and beaches and woodlands. Enquiries can be made to the Field Studies Council, Tavenersmead, Keston, Kent.

Everyone who wants to work in the field can find something useful to do whatever his natural bent and his training, since the range of research is vast and the problems diverse with such varying degrees of difficulty. This opportunity has been greatly extended by the increasing importance of ecology which is a distinctive point of view in the approach to field biology. In its most general sense ecology may be defined as the study of plants and animals as they live in their natural homes. The growing popularity of the subject in this country represents a breakthrough from the confinement of serious work in biology to the laboratory and museum. These are still of course absolutely necessary but the primary place in which to work at ecology is the field.

Bird watching. The pleasure of bird song and the sight of their activities is a common one for most of us. From this point many are prompted to make a closer study of birds and their habits. To get the most pleasure it is a great advantage to turn for advice to those who have had a wide experience. The enthusiast will thus become equipped with some knowledge of methods of bird watching, how to make field notes and keep records, hides, identification tables of family likeness, migration sanctuaries, bird photography and the structure of the bird.

Bird watching is not confined to those who live in the country. London has probably more bird watchers than any other part of Britain. With the possible exception of the parish of Selborne in Hampshire immortalised by Gilbert White, London has the longest continuous history of ornithological observation in the British Isles. Groups of enthusiastic naturalists have collected a mass of detail about wild birds and their habits in London. The list of London birds is not only extraordinarily large but also contains many rarities and many birds of great scientific interest like the black redstart and the little ringed plover. There are also special London problems like the roosting of starlings in central London and the origin of this startling population. The reservoirs and the river the commons and woods and parkland around London offer pleasant places for observation. The London Natural History

Society (headquarters the Natural History Museum, Cromwell Road, S.W. 7) has as its chief object the study and enjoyment of natural history in the London area.

Fishing Nature Reserves. The Nature Conservancy welcome visitors to National Nature Reserves within the limits set by the Conservancy's own responsibilities towards these lands and their plants and wild life. The Reserves are maintained on behalf of the nation to conserve their natural fauna and flora and so far as possible to enhance their interest and value to science. Many Reserves are accessible without formalities elsewhere a permit is required. A list of the Reserves is obtainable from the Conservancy, 19 Belgrave Square, London S.W. 1 or in Scotland from 12 Hope Terrace, Edinburgh 4. There are some eighty National Nature Reserves. The largest in Britain is the Cairngorms in Scotland, nearly 40,000 acres with fauna rich and a variety of species from wild cats to golden eagle and a diverse flora which includes the arctic alpine plants of the corries, screes and exposed summits.

The Council for Nature. If you are interested in any aspect of natural history—for example in plants, birds, rocks, insects, trees, butterflies or natural history photography—you will have no difficulty in finding the address of your local history society of which there are a very large number. The local public library would doubtless give you the address you want, or you could enquire from the Council for Nature, Zoological Gardens, Regents Park, London N.W. 1, which over two hundred organisations belong. These include the Royal Society for the Protection of Birds, The Lodge, Sandy, Beds, which has upwards of 53,000 members and runs the Young Ornithologist's Club for young people interested in bird watching. It manages over 40 nature reserves most of which are open to the public and runs a film library. The Council links amateur and specialist in the study of natural history and the conservation of wild life. It has an Intelligence Unit which is ready to deal with requests for information on field natural history in the United Kingdom and its Film Officer will advise on what natural history films are available and on likely sources for photographs of any British wild animal or plant.

Netball.

Netball, which is played exclusively by women, is similar to basketball (q.v.) but it is played seven a side, does not allow substitutes, and the goals have no backboards. It is almost always played outdoors on asphalt or grass. Details of school, youth, county and national competition may be obtained from the All England Netball Association, 26 Park Crescent, London W.1N 4DL.

Nine Men's Morris. See Old English Games and Customs.

Old English Games and Customs

The story of England had its beginnings a very long time ago and many of England's present day customs, recreations, sports, and games can be traced far back in that story. Some of course have undergone very considerable changes but the links with the past are still clear.

On 1 May for instance girls still awake in some villages to the realisation that they are to be May Queens and to reign for a day though they may not realise that they are preserving a custom that can point to origins in the days of the Druids and that in Tudor times, would have sent them and their fellow villagers out to spend the preceding night in the woods, gathering branches of trees and flowers with which to decorate their houses. Maypoles and morris dancers also belonged to May Day and they can still be seen in England, and not only on that day.

More local even quantier but equally traditional is the trial for the Dunmow Blotch of Bacon in the village of Dunmow in Essex. The original conditions offer this award to any married couple who will go to the twelfth century Augustinian priory and there kneel on two sharp pointed stones and swear that they have neither quarrelled nor repented of their marriage within a year and a day of its celebration. This award has lasted into modern times not annually it is true but then it never was given annually for it was instituted in 1244 and first claimed in 1445.

One annual event that is as traditional as it is strenuous is the Whit Monday cheese chase at the village of Brockworth near Gloucester. Records of this go back to the days of the Stuarts for that was when they started to keep records of a custom that was already old then so old that its origins are unknown though they had to do with the villagers' cattle grazing rights. A massive round cheese is rolled down nearby Coopers Hill which has a gradient of one in four throughout its 150 yards and with a certain amount of risk to life and limb the chasers tear down after it the cheese being the prize for who ever catches it. Sometimes the cheese hits a bump and literally leaps out of reach over the hedge at the bottom of the hill, but the chase continues the prize going to the first pursuer to reach the hedge where catchers wait to halt the headlong rush of the runners. Despite the obvious dangers the records to date mention nothing worse than a sprained ankle.

This brings us to sports and games and though today's most popular game Football is in any way like its present form a comparatively recent growth it can perhaps claim some relationship with Harpastum and Campball which existed before the Norman Conquest and it was one of the popular recreations banned in the interests of Archery. The football of those and later days however took the form of struggles between whole villages the players battling *en masse* over a cross country course of several miles. People past whose houses the battle was likely to rage prudently barred and shuttered all windows and doors awaited the cessation of hostilities with anxiety and probably helped to push this particular custom into oblivion.

The oldest English games are old indeed and cricket too had remote ancestors from which the descent to today can be traced more directly. They included Bat and Trap, Creag Cat and Dog and Rounders. In Bat and Trap the batsman hit a ball released from a trap between two posts. His opponent rolled it back underarm at the trap flap. If he knocked it down the batsman was out; if not the batsman scored one run and had another hit. This game is still played in Kent. Creag which was played at the time of Edward II used a curved stick called a *creag* as a bat and a tree stump as a wicket. Cat and Dog which came later was a game for three two batsmen defending holes 18 yards apart and trying to hit away the piece of wood that the third player aimed at the holes the bats being the dogs and the piece of wood the cat. It is worth noting that Baseball's accepted ancestors are games called One Old Cat and Two Old Cat which clearly indicates a common origin for Cricket and Baseball. Some of the games in Cricket's ancestry remained popular after Cricket arrived and Rounders is still a popular children's game.

The beginning of athletics can also be found in old England. Putting the weight and casting the bar a forerunner of throwing the hammer were popular with the courtiers in Tudor days while other events including javelin throwing were practised by ordinary people of the same period. Later the early hammer throwing spread beyond the Court and was even attempted by women which modern hammer throwing is not.

Tournaments and jousts were popular from the Middle Ages until Tudor times. These were combats between mounted men a joust being single combat while a tournament involved many contestants. They were succeeded by dismounted combats which still take place today in the sport of Fencing. Those taking part

in tournaments and jousts were required to swear an oath to the effect that they were competing purely for sport and those taking part in the Olympic Games and certain other big sports meetings to day swear an almost identical oath. Somewhat similar to jousting but not restricted, as jousting was to the nobility was Tilting at the Quintain which was practised both mounted and on foot and in which a lance was thrust at a wooden target which if not struck accurately swung round and struck the tilter.

Other old games clearly the ancestors of modern ones included Handball which became Fives but which is still handball in the United States. Battledore and Shuttlecock still a children's game but now developed by adults into Badminton and Shovelboard an elaborate game for the nobility which consisted of sliding weights down a long table marked with lines and which is certainly a forerunner of Shove Ha penny. Another probable ancestor of Shove Ha penny was Squalls in which a coin was placed in the centre of a round table and players tried to push their squalls or discs as close to the coin as possible distances being measured by an instrument called a *swoggle*. Also known as Skayles and Keels this game appeared in the sixteenth century lasted into the nineteenth century and under the name of Keels achieved a poetic mention in Sidney's *Arcadia*.

Archery Archery goes back hundreds of years to the days when the bow was the chief weapon of war and because of that practice shooting and contests were officially encouraged or encouraged in fact to the extent that other popular recreations like Football Quoits and Bowls that might have interfered with it were banned though the bans were always largely ignored. Eventually the bow disappeared from the battle fields but to this day it has remained popular as a means of recreation and sport. Through the centuries archery contests were generally of three kinds shooting at a mark or target shooting purely for distance though this was more popular abroad in countries like Turkey than in Britain and shooting at rovers in which two or three archers would cover a cross country course taking it in turns to select a mark at which to shoot. To day archery which retains enough of tradition in its terminology to remind the archer that he is following in a very long line consists of shooting at a target containing rings coloured going from the centre outwards gold red blue black and white the values being respectively nine seven five three and one.

Knur and Spell Knur and Spell belongs to Lancashire and Yorkshire and originated in a children's game called Trap and Ball. The player uses a wooden club the striking end of which called the *pommel* is shaped something like a bottle though it has a flat hitting surface with which to hit a small ball which he himself releases from a trap by means of a trigger. The ball which is the knur weighs $\frac{1}{2}$ ounce measures 1 inch in diameter and was originally wooden though later porcelain was used. The trap is the spell and consists of a small brass cup with a strong spring which is kept down by the trigger. The fixing of the spell is an elaborate process requiring the use of a spirit level and when it is in position a player is allowed 10 minutes to adjust the tension of the spring. Players generally have their own spells. Each player has five consecutive hits or rises and scores one point for every 20 yards covered.

Marbles Marbles is supposed to have been played in ancient Egypt but its popularity with adults as well as children in England of the Middle Ages entitles it to count as an old English game. Marbles are often made of clay but better ones are glass and the best are pure marble. These are called *allers* or *alley taws*. There are several games of marbles but they all involve the aiming of a marble at a target which may be another marble or an opening by bowing or shooting it along the ground. In shooting

the marble is held between the thumb and fore finger with the knuckle of the forefinger on the ground and is then flicked away

Perhaps the best known game is Ring Taw in which players shoot from one circle at marbles placed in another about 6 feet away. Fortifications and Increase Pound use concentric circles players shooting at marbles in each circle in turn. Three Holes and Handers involve shooting at holes in the ground. Arch Board or Bridge at arches in an upright board and Die Shot at another marble on which a numbered die is balanced

Nine Men's Morris. Nine Men's Morris is a fourteenth-century game for two usually played outdoors on a diagram marked on the ground but sometimes played indoors on a board. The diagram consists of three squares drawn inside each other. In addition to the outlines of each square there are lines from the centre of each side of the innermost square through the centre of the sides of the middle square to the centre of the sides of the outermost square. The corner of each square and the centre of each side are the 24 points of importance in the game. Each player has nine men often counters and they play in turn placing a man at an unoccupied point and endeavouring to place three men in one row continuing when all the men are placed to try to form rows by moving men along the lines. The completion of a row entitles a player to remove or pound one of his opponent's men the object of the game being either the capture of all the opposing men or blocking them so that they cannot move. The game has many variations and many names including ninepenny morris, fivepenny morris for a version played with five men, and maris maris marrels morris morris and miracles all for a version played with three men

Pall Mall. Two London thoroughfares Pall Mall and the Mall are reminders that Pall Mall was once popular. Often described as a fore-runner of Croquet it was really more like a form of Golf a game that arrived at about the same time both having a common if remote ancestor in the Roman game Paganica. In Paganica players walked across fields hitting a small leather ball at trees with a curved stick the object being to reach the target in the fewest possible strokes. It was played by country people whereas pall mall which achieved rapid popularity in the seventeenth century was a game for the nobility though other people played simplified versions of it. Pall Mall was played in special alleys sometimes $\frac{1}{2}$ mile long and often surrounded by walls. A boxwood ball a foot in circumference had to be played down the alley in which were a number of iron arches in the fewest possible strokes. The player drove off as in golf but on reaching the arches not only changed his club but also substituted a small steel ball for the boxwood one

Quoits. Dating back to the fifteenth century Quoits is one of those ancient games that had the distinction of being banned because its popularity was such that it was believed to be keeping people from archery practice. The ban was not effective and it continues to this day though it is now less played than it used to be Scotland, the North of England and Suffolk being perhaps the last main strongholds. The pitch consists of two circles or squares of clay 18 yards apart and each having in its centre an iron pin called the hub 1 inch of which remains above the surface. The quoits are iron rings with a diameter that must not exceed 8 $\frac{1}{2}$ inches. The weight is not fixed but is often 8 lb or more. The object of the game which can be either singles or doubles is to throw the quoit over or near the hub from the opposite point 18 yards away one point being scored for each quoit nearer the hub than the opponent's quoits, and two being awarded for a quoit that drops over the hub called a ringer. No points are awarded if opposing quoits are the same distance from the hub and none are awarded if each side has a ringer. A game is 11 points in singles and 15

points in doubles. Quoits developed from pitching actual horseshoes and to this day some players make their first practice attempt at it with horseshoes

Shove Ha penny. Shove ha penny an old English game that is still popular uses a cushioned wood or slate board divided by parallel lines across it into nine beds in the halfpennies may be actual halfpennies but are generally round metal discs. The object of the game is to shove the half pennies into one of the nine beds the shoving usually being done with the ball of the thumb though any part of the hand may be used. First turn is decided by shoving halfpennies at the number nine bed the best attempt winning. A turn consists of five halfpennies and the winner is the first player to shove three halfpennies into each bed halfpennies that touch the cushion not counting. Should a player place more than three half pennies in any bed his opponent can claim the excess if he needs them but cannot win the final point of a game in the way. Push Penny a similar game using three coins is played in some parts of the country mainly in Lincolnshire

Stoolball. Yet another ancestor of cricket Stoolball is still a popular girls game. The wicket is a board a foot square on a pole 4 feet 8 inches high the bat has a round striking surface and the ball is rubber. Wickets are 16 yards apart and eight balls constitute an over

Orienteering

A sport long popular in Scandinavia orienteering as practised in Britain—and it has really caught on—is a combination of walking cross country running and finding one's way about the country by using maps and compasses. Competitively it is usually played eight a side but plenty of fun can be had at the beginning if played in pairs. It is suitable for people of all ages and details may be obtained from the British Orienteering Federation 2 Stanley Villas Houghton nr Preston Lancashire

Pall Mall. See Old English Games and Customs

Parachute Jumping

Parachute jumping is generally regarded as a last resort safety measure to be undertaken only in a supreme emergency and with considerable anxiety but it is now also a recreation and a competitive sport practised entirely voluntarily and for enjoyment. This form of jumping may be said to have grown out of the Second World War in which jumping was used to a far greater extent than ever before and not only for escape in an emergency. Now international competitions take place and the sport has an enthusiastic following in Britain.

Parachute jumping as a sport involves jumps of particular kinds, including landings in a certain area, marked by a circle, and demonstrating turns and body control in the air the parachutist regulating his direction by pulling down the lines of the parachute. Jumps of this kind may be made from about 8000 feet.

The first point that occurs to many people when they think about Parachute Jumping is that it is extremely dangerous. However those who jump as a recreation maintain that this is not so and that it is about as dangerous as skiing. Injuries are few and slight and in three years, none of the hundred-odd members of the British Parachute Club of Fairoaks Surrey suffered anything worse than a sprained ankle. The parachutes used are so reliable that they still work even if they have been badly packed. A parachute consists of twenty-eight sections, called gores, each divided into four panels, so that even if a hole should stretch right across one gore which is rare, the remainder of the parachute remains intact and will bring the jumper down safely. As an additional precaution, jumpers wear a small reserve parachute on the chest but this is hardly ever needed.

Training which generally takes place at week ends, starts with a period of learning how to fall, how to judge wind direction and speed, and how

to pack a parachute. The first actual jumps are from 2 000 or 2 500 feet. Both men and women take part in Parachute Jumping.

Parachutists must be licensed by the Civil Aviation Department of the Board of Trade and they must produce medical certificates of fitness. Third party insurance is also compulsory but this is automatically covered by membership of the British Parachute Association. Leading centres of Parachute Jumping are at Blackbushe Airfield Hampshire Thruxton Wiltshire Manchester and Gleneagles.

Patience

Patience is a card game for one person and though there are few different games for one there are countless different forms of Patience. There are some using one pack and others using two, almost all of them starting with the setting out of the cards on the table according to fixed rules and having as their object the building up of the four suits on their aces.

The game that might almost be called the basic form of single pack patience starts with a row of seven cards, only the left hand one being exposed. Underneath this, and overlapping it, comes a row of six cards with the left hand one exposed and so on down to a row consisting of only a single exposed card, the exposed cards being left uncovered in each decreasing row. The object is to take out first the aces and then the cards from two up to king, building each suit on its ace. From the lay out, exposed cards can be moved when it is possible to put one on a card one pip higher in value of the opposite colour, when any card left uncovered by an exposed card can itself be exposed. The undealt cards can be played three at a time, the top one of each three being playable with the one underneath becoming playable if the top one is in fact played. The undealt cards can be played through three at a time in this manner as often as desired. A slight variation of this game allows the undealt cards to be played through one at a time but this can be done only once.

Another single pack game starts with a row of nine exposed cards with below it and overlapping a row of eight and so on down to one, all the cards being exposed and the right hand one being left uncovered in each decreasing row. The remaining seven cards form a separate row at the bottom. The object and the move are the same as in the previous game, only one card being moved at a time and any card being eligible to fill any vacancy that might occur in the top row. Cards in the separate row can be played as required but once in the lay out they must remain there. This game is called King of the Belgians, and the last seven cards are referred to as the Belgian Reserve.

One to Six is a two pack game. The player deals out a row of four cards, then discards two to a rubbish heap and carries on like this until all the cards have been used. If however while doing it he comes across any aces or kings, he takes them out up to one of each from each suit, subsequently also taking out any that will fit on to these, building up from the aces and down from the kings. Then he goes through the rubbish heap, extracting any cards that will fit on the eight piles. The dealt out cards, with the rubbish heap cards, are then dealt again in the same way, the object being to complete the eight built up suits in three rounds of dealing.

Polo

Polo, one of the oldest of all games, originated in Persia, then spread in one form or another to China, Japan, and India, eventually being brought from India to England by cavalry officers in the second half of the nineteenth century. Later it was enthusiastically taken up in the United States and Argentina. Played four a side and mounted on a pitch that should measure 300 yards by 180 yards, its object is to score goals by hitting a 5-ounce ball through goals 24 feet wide with a

stick consisting of a long cane fixed at a slight angle into a wooden or bamboo striking head. The game is divided into periods called chukkas, the number of periods varying slightly as may be agreed for particular games.

Formerly Polo was a game for the wealthy for it entailed owning and maintaining a string of trained ponies. In recent years however certain stables and riding schools have provided facilities for playing and practising Polo and these facilities include the hiring out of ponies. This apparently simple and obvious step is actually quite a revolutionary innovation that has brought Polo within the reach of almost anyone who wants to play and thereby increased the popularity of an ancient and exciting game that might otherwise have died out because of the expense involved.

Pony Trekking

Pony Trekking as an organised recreation originated in Scotland in 1953 though something similar was known in India before that. The word *trekking* itself is Afrikaans. Chance and coincidence played a part in starting Pony Trekking at least on a larger scale than might otherwise have been the case. The first trek was at Newtonmore, Invernesshire and was partly organised by officials of the Scottish Council of Physical Recreation. At about the same time at Aberfoyle, Perthshire, *Rob Roy* was being filmed and many townspeople who came to watch expressed great interest in the horses. This led to the planning of a trek in that area, the organisers of which knew nothing of the Newtonmore venture though they subsequently heard of it and received advice from its organisers. The first trek from this second centre took place in 1954. Now there are about 70 approved centres mainly in Scotland, Wales, the West Country and the Lake District though there are also some in Ireland and on the Continent. Approved incidentally means that they are inspected every year by the Scottish Council of Physical Recreation or the Ponies of Britain Club and hold Certificates of Approval from one or other of those bodies.

Pony trekking consists of riding over the hills and moors through forests and along ancient tracks at a walking pace for if you ride faster than that you cease to trek and begin to hack (see riding). No experience whatever is needed and the complete novice or child who has never ridden at all can enjoy pony trekking from the start. During the first two days of a trekking holiday beginners will be given some elementary instruction in saddling, mounting and starting and stopping the horse and then they will start with short treks of from five to ten miles.

There are two forms of pony trekking, day trekking and post trekking. Most treks are day treks consisting of circular all day tours starting and finishing at the centre. Post treks last for several days and include stopping at a different post or centre each night. There are comparatively few post treks partly because they are only suitable for experienced trekkers and partly because of the difficulty of obtaining accommodation for one night only during the height of the holiday season.

The pony trekking season is mainly from May until September though some centres are open from March until December and there is the occasional one that is open all the year round weather permitting. Details of approved centres including those especially suitable for children can be obtained from the Scottish Council of Physical Recreation, 4 Queensferry Street, Edinburgh 2, the Scottish Tourist Board, 2 Rutland Place, West End, Edinburgh 1, or the Ponies of Britain Club, Brookside Farm, Ascot, Berks.

Potholing

Potholing might almost be described as mountaineering in reverse for it consists in the exploration of underground passages, maybe to depths of several hundred feet. Besides being a

challenging recreation it offers opportunities for specialisation of diving, photography, surveying and can yield useful information in connection with water supplies, water pollution and hydro-electric schemes.

The main potholing centres in Great Britain are in Yorkshire, Derbyshire, the Mendips and South Wales regions where rainwater carrying dissolved carbon dioxide from the air has attacked the massive limestone rocks and the drainage has passed underground. The nature of the passages varies with the geological area. A system containing many horizontal passages is known as a cave, one with appreciable vertical drops as a pothole. Drops or pitches are comparable to waterfalls in a surface stream and often carry an active stream themselves. A pitch may be over 200 ft deep and the system may reach a total depth of 600 ft or extend for several miles. Potholers make their descents by means of flexible ladders constructed from steel wire and aluminium alloy. Recent developments include the adaptation of skin diving techniques and equipment to enable the more arduous passages to be explored.

The underground world is far more varied than one would expect. The potholer's headlamp picks out beautiful shapes formed by dripping water containing dissolved limestone—stalactites hanging like icicles, stalagmites growing from the cave floor, curtain-like draperies, in petrified modern and smooth pebbles (known as cave pearls) in pure white, orange, green and black according to the metallic impurities.

The beginner is strongly urged to join a club which organises trips and training and provides the proper equipment. Potholing could be dangerous to the novice exploring alone, but as a club member he (she) has the opportunity of taking part in an exciting and exhilarating sport one of the few left that gives the thrill of original exploration.

Public School Football

All the forms of football popular to day grew out of the games played at various English Public Schools a century and more ago. These games differed widely, the rules often depending on purely local considerations imposed by the available space. The rugby game (*q v*) in its modern form is of course still played both at that school and far beyond it, and other games that still survive at the schools that originated them are the Eton Field Game, the Eton Wall Game, the Harrow Base Game and Winchester College Football.

Punting

Punting consists of propelling a long, narrow, flat-bottomed boat with a pole, the punter standing up and it can be either a pleasant, leisurely recreation or a fairly strenuous competitive sport. The sporting side is governed by the Thames Punting Club which has headquarters on the Thames at Staines in Middlesex. Women, as well as men, take part in competitive events.

Punting as a sport has the unique distinction of being confined not only to one country, Britain, but to one river, the Thames, though in some parts of the world boats poled from a standing position are used for various purposes. There have been rumours that Japan has or had, a similar sport, but these have never been authenticated.

Quots See Old English Games and Customs.

Race Walking See Athletics, Walking.

Rackets

Rackets is a fast racket and ball game played on a court measuring 62 feet by 31 feet and rising walls. A game consists of 16 points, unless 13 all is reached, when the non-server can set the game to 3 or 5 or 14 all is reached when the non-server can set the game to 3, the game going to the first player to score the prescribed number of points.

Only the server scores, the receiver taking over service when he makes a winning shot. When served, the ball must strike the front wall above a line called the cut line before striking any other part of the court, but in play it may be played either on the volley or after one bounce. If a player impedes his opponent it is a let and the point is re-started.

Real Tennis

Tennis sometimes called Real, Royal or Court Tennis is a court game played with rackets and balls that has been called the King of Games and that was once certainly the game of kings. Henry VIII played at Hampton Court where there is still a fine court and a club, but the first kings to play were of France where the game originated.

It is a complicated game and no description could give anyone who had never seen it an accurate idea of what it is like. Most racket and ball games use either a net over which the ball is hit or walls against which it is hit, but tennis uses both. Also in most racket games, players change ends after so many games, but in tennis they may do so during a game. Matches are in games and sets, a player winning six games completing a set towards the two out of three or three out of five that will make the match.

There are not many tennis players in the country—there are only about a dozen courts—and very few women have ever played. People who do play, however, most of whom play other games as well, are almost unanimous in voting it the best of all games.

It is said that the term *love* used in so many games to indicate nought comes from tennis, the original French term being *l'œuf* which in that language actually means egg, an egg being of course something like the figure used for nought. This derivation is not sufficiently well documented to be accepted as definite fact, but it is interesting to note that in cricket (*q v*) the term used for a score of nought is a duck or in full a duck's egg.

Revolver Shooting See Rifle Shooting.

Riding and Show-jumping

The almost complete disappearance of the horse from everyday life has been followed by an increase of interest in riding as a recreation. This is at least partly due to the great attention paid in recent years by both Press and television to one particular branch of horsemanship, show-jumping. Before learning to jump, however, it is necessary to learn to ride, and many people never go and have no wish to go beyond the ordinary unspectacular riding for pleasure that is called hacking.

A great deal has been said and written about correct riding style, but in actual fact, there are many different styles. The cavalryman, for instance, bends the leg to some extent, the Red Indian bends it to a much greater extent, more or less in the style that has been adopted by American jockeys and the cowboy rides with an absolutely straight leg. Yet all these are expert horsemen. To assist in acquiring the normal English style, which is very close to that of the cavalryman, there is an old fiddle that is now much less heard than it used to be, but is probably none the less helpful or accurate for that. It runs: "Your head and your heart keep up, Your hands and your heels keep down, Your knees keep close to your horse's sides, and your elbows close to your own. Old or not, anyone who learns it and then builds up a certain amount of experience of putting it into actual practice is well on the way to becoming a rider."

Those who feel they would like to combine their riding with something competitive might start with gymkhanas, which are sports meetings that generally include mounted equivalents of such novelty events as obstacle races and needle threading races. For the more ambitious, gymkhanas could even be the first step towards the top-class competitive sport of show-jumping.

Show jumping A show jumping contest is a mounted competition over a circuit of jumps which the entrants attempt one at a time each having the field to himself or herself and being free to concentrate entirely on the jumps without having to worry about other riders. The jumps which have to be taken in a certain order are of many kinds including fences double fences walls and water. Scoring is by points against called faults so many being debited against an entrant for falling knocking down an obstacle or displacing part of it refusing and other mistakes. Though the event is in no sense a race there is normally a time limit that must not be exceeded and in some events bonus points are awarded for fast rounds. Show jumping is not restricted to riders who own their own horses for some owners do not want to compete themselves and are only too pleased to let good horsemen take their jumpers round for them. Incidentally in experienced riders taking up jumping for the first time will probably find it advisable to make some slight changes in their method of sitting in the saddle. Jumping needs a firm seat and the novice rider may find it necessary to shorten the stirrups a little.

Alfred to show jumping and coupled with it in the difficult three day competitions is dressage. This is simply a mounted display revealing that the horse is obedient balanced supple and in a word trained and is a simplified form of the better known haute école or highly schooled riding. Good riders who seek absolute perfection can if they are willing to pay for it take an intensive course of haute école riding and all forms of horsemanship at the most famous of all riding schools the Spanish Riding School in Vienna. Courses which are conducted in German consist of eight hours training a day for six months and informality is not encouraged the regulation dress for students being a bowler hat black jacket and white breeches. Riders who fall are immediately assisted by an attendant armed not with a stretcher but with a clothes brush. See also pony trekking.

Rifle Shooting

Considered as a sport rifle shooting which might almost be called the modern equivalent of archery had its origins in virtually the same conditions and circumstances that had popularised the older weapon five hundred years previously though unlike archery it did not enjoy legislation aimed at abolishing other recreations in its favour. Both were encouraged because in their respective periods efficiency at them meant not only success in competitions but also the most effective defence in time of war the great period of the rifle's encouragement for this reason being the latter half of the nineteenth century. Archery as a sport survives to the present day and rifle shooting as a sport continues though it can no longer be regarded as the most effective weapon.

With a normal rifle with a calibre of about 300 inch competitive shooting is at ranges from 200 yards to 1000 yards and there are many competitions the greatest of them being the annual contest at Bisley Surrey for the Queen's Prize. Almost equally popular however is small bore shooting with a calibre of 22 inch and this too offers many annual competitions.

Revolver Shooting Revolver shooting often called pistol shooting is also a competitive sport and a very difficult one. Impressions gained from cinema and television screens might lead anyone who has never fired one to think that the revolver is an easy weapon to fire without fuss and with devastating effect. It is the very reverse of this. It is fired not from the hip but with the extended arm raised which is how in real life it was generally fired in the old West. It is extremely difficult to hit even a man size target at 10 yards and very few people can call themselves good revolver shots, just as few of the old Westerners were good revolver shots. The difficulty is caused by the tremendous kick of a weapon that is held not by both hands and pressed into the shoulder as a rifle is but by one

hand. Revolvers have sights but the normal method of aiming is by using the instinctive pointing sense which is based on the fact that if you point at an object in the ordinary way you do in fact point accurately. This applies when pointing a revolver. As with rifles small bore target shooting in which sights are used is popular.

Rink Hockey See Skating

Rock Climbing See Mountaineering

Roller Skating See Skating

Rowing

Rowing meaning simply taking a boat out on the sea or a river for a short period is a pleasant recreation and a healthy exercise but competitive rowing is one of the most strenuous of all sports.

A racing oarsman either *rovs* which means that he uses one oar or *sculls* which means two oars. Races are of various kinds the best known being for crews of eight oarsmen with a cox. Then there are races for crews of four with cox and for crews of four without cox. There are also events for pairs with cox pairs without cox double sculls and single sculls. Eights fours and pairs row while double and single scullers of course scull. In fours and pairs without cox and in all sculling the oarsmen steer themselves.

Race Rowing is mainly a river sport but there are races on the sea. For these crews are usually fours with cox and they use heavier boats than the normal racing shell. (See also Boat Races)

Rugby Fives See Fives

Rugby Football

As its name implies Rugby football is based on the game played at Rugby School in the days when football was not organised and various schools played to their own rules. The story of how the Rugby game originated is well known and widely accepted but it is definitely not accurate and possibly almost entirely apocryphal.

The story is that in 1823 a boy named William Webb Ellis disregarded the rules of that time by handling the ball and that handling was subsequently made legal. In fact handling the ball by catching it was allowed at Rugby before 1823 so if Ellis was responsible for an innovation it was not by handling the ball but by running with it after catching it. Running with the ball certainly became and remains the leading feature of Rugby football but the story that Ellis was responsible though commemorated by a plaque at the school was first heard years after Ellis's death and he never knew of the fame that became his. He was definitely at Rugby at the time though and a few years later he played in the first ever Oxford and Cambridge cricket match.

The spread of the game beyond the school that originated it has led to not one but two games of Rugby football, Rugby Union and Rugby League. About twenty five years after the game had become organised with the Rugby Union as its governing body there was a dispute on the question of legalising payment for time lost from work by players. The Union would not agree to this so twenty two clubs mainly in Yorkshire seceded and formed the Northern Union now the Rugby League. Both bodies originally played the same game but now after over sixty years of independent existence during which each has made various rule changes there are some important differences.

Rugby was originally played twenty a side but it is now fifteen a side in R.U. and thirteen a side in R.L. the positions being seven backs and eight forwards in R.U. and seven backs and six forwards in R.L. Played on a pitch marked out as in the diagram and with an oval ball Rugby is mainly a handling game the chief object being the grounding of the ball behind the opponents'.

GAMES AND RECREATIONS

though there is a top layer of clubs using part time professionals

Mention of sailing tends perhaps to conjure up visions of large graceful craft beautiful to see, but clearly to be owned only by the wealthy. Sailing to day though is very different from that. It is usually done in small boat, many of them wholly or partly built by their owner. At first glance the building of a boat might seem a tremendous and highly skilled task, but in actual fact it can be as big, and as hard on as spread out as easy as the building of a house. Some amateur builders start from the very beginning, acquiring the various materials needed bit by bit, and gradually bringing their boat into being. However, ever those who either lack the time for this or

The game is started and restarted after a core by a kick off from the centre and the e after the ball may be advanced by kicking or carrying. It may also be passed from hand but not forward. Ball carriers may be tackled and thrown down and they may hand off tacklers.

Indicates Post with Flag Length and breadth of field to be as near to dimensions indicated as possible

Goal dimensions—10 feet is taken from the ground to the top edge of the crossbar and 18 feet 6 inches from inside to inside of the goal posts

with the unclenched hand. A frequent method of restarting after a stoppage is the scrum, in which the forwards bend down and push against each other three from each side constituting a front row and the remainder two subsequent rows. The ball is then put into the tunnel between the front rows, the centre man of each the hooker endeavouring to gain possession by hooking it back into and generally getting through the scrum. In this method of restarting the scrum whenever the ball goes over the touch line but in R U the ball is thrown in straight along a line out of both sets of forwards unless the side whose throw it is demand a scrumage. In R L kicking the ball straight out over the touch line is allowed only from a free kick the penalty being a scrumage at the point from which the ball was kicked. The effect of this is to suffer the team that has two halves that R L faster and more open and the ball is more continuously in play. A game lasts for eighty minutes, divided into two halves.

In addition to Britain both forms of Rugby are played in France, New Zealand and Australia, and R U is played in South Africa. Both codes also have other smaller outposts in various European countries, and there are minor R U centres in North and South America. R U is entirely an amateur game and R L primarily so.

doubt their ability to construct a boat in which they would feel safe on the water can buy complete boat building kits and they can buy them from a variety of construction they choose from. They can buy a complete kit except for a coat of paint. It is more economical to build a boat than to buy one complete and ready for launch. The owner can enjoy the early stages of construction and the earlier the stage of construction at which the owner takes over the greater the savings. Some owners claim that they enjoy the building as much as the sailing and it is probably true that the owner who has done some work on his boat however little takes more interest and pride in the finished article.

The fact that boat building is now within the reach of practically everyone means of course that the end to which it is a means Sailing is also within the reach of practically everyone for few people are far from some suitable stretch of water. Where there is sailing there are clubs which the boat owner can join for quite reasonable fees and which provide either sheltered moorings or dinghy parks where the boat can be kept.

Intending boat owners or builders should visit London's annual Boat Show or the Dinghy Exhibition at Crystal Palace National Sports Centre. For training, young people should get in touch with the Sail Training Association, while for over

17 s we now have the National Sailing Centre' at Cowes run by the R Y A. and the C C P R

Eventually the small boat owner may want to try racing his craft and there are many events for boats of all classes and sizes

Skating

At first glance ice skating would not appear to be a normal activity for British people for it is a part of winter sports (qv) which are possible in Britain only rarely and to a very small extent and it was formerly restricted to brief periods when rivers lakes and ponds were frozen. Despite this however the people of this country have always appeared to possess a natural talent for it and they have practised it whenever opportunity offered. The history of British skating goes back a very long way and includes occasions when skating was possible and took place on the Thames as well as many more regular instances in the Fen district and other places. In recent years this wish to skate on ice has been catered for by the opening of many indoor rinks which make the skater independent of weather and daylight and enable skating to be carried on throughout the year.

Many people ice skate just for recreation health and amusement but anyone keen to carry skating a stage farther and acquire a higher level of skill can find a wide range of opportunities from which to choose. Figure skating is very popular and for those anxious to test their skill at it there is a series of medal tests in which the skater is not in competition with anybody but is attempting only to reach a fixed standard. Beyond these there are many competitions and championships. Dancing on skates also attracts many people and also offers those interested standard medal tests and competitions.

Another popular skating activity is speed skating which takes place indoors and whenever possible outdoors as well though the methods and techniques of the two forms of racing differ widely. Outdoors the skaters normally race in pairs though each man is timed and is actually racing against the whole field. Much of the racing is on long straight stretches of ice. Indoors skaters race perhaps four at a time and are directly opposed to those on the ice with them. These races are on small tracks a lap sometimes being no more than 130 yards. Standard outdoor distances range from 500 to 10 000 metres while indoor races go from 440 yards to 2 miles. There are also indoor relays generally of 3 miles in which teams of four race on the Madison method relieving each other not at fixed points, but at will. In addition to competitions and championships speed-skaters also have their standard medal tests.

Ice however is not the only surface on which skating takes place for following an unusual history roller skating also maintains a large following. Roller skating was originally introduced long before the arrival of the indoor ice rinks purely to provide ice-skaters with some kind of substitute when no natural ice was available. It progressed by fits and starts, varying from extraordinary crazes when it seemed that everybody was roller skating to periods when nobody appeared to be doing so. Eventually it settled down to a steady existence as a popular recreation in its own right that has in no sense been pushed into the background by the increased facilities for ice skating. The opportunities it offers are almost identical with those of ice skating for they include figure-skating dancing and speed skating with championships competitions, and standard medal tests in all branches.

Both forms of skating also offer a team game, and in both it is hockey. Ice hockey which is

called simply hockey in Canada where it originated and the United States is played six a side with substitutes permitted and with a rubber disc called a puck instead of a ball. It first began to win popularity in Britain soon after the First World War and since then has had rather a chequered career helped forward by the semi-professional players from Canada who play in the National League teams and held back by the lack of facilities for British youngsters to practise for practice sessions mean closing rinks to all the other forms of skating for certain periods. The game should however survive for there is a definite demand for it.

Roller hockey generally known as rink hockey bears a closer resemblance to its parent game outdoor field hockey than does ice hockey. It is played with a ball and is five aside with one substitute permitted. Its popularity is such that it is now played throughout the year.

There is a form of hockey on ice that closely resembles outdoor hockey. This is Bandy which originated in England but is no longer played here though it is popular in Sweden and the USSR. Some other games have been tried on skates from time to time. One is Badminton which has been played on ice but only as a stage exhibition. Basketball on roller skates has been tried in several countries and might well develop and spread.

Skating is not so much a recreation sport or game as a whole series of different recreations sports and games. Each has its following and while there are enthusiasts who are interested in both ice and roller skating or in more than one branch of one or both of them there are many ice skaters who have no interest in or knowledge of roller skating and vice versa and many keen supporters of just one branch of skating who hardly know that the many other branches exist. It is of course quite possible to take part in both ice and roller skating and in more than one branch of skating and greatly to increase one's enjoyment by doing so.

It is not particularly hard to learn to skate. It requires strong ankles a good sense of balance and plenty of confidence and it is possible to start practising at least to a limited extent at home for instance by getting used to standing on skates. Skating is probably more easily mastered when young but many adults have successfully taken it up.

Skittles

Skittles has not so been played in England since the 13th century and came from Germany where it was known as *Kegel*. There are several versions but all consist in throwing a ball down a level alley at a set of pins.

In English skittles the ball is a flat sided object called a *cheese*. In German and Dutch Skittles a round ball is used. Both types of ball weigh at least 10 lb and sometimes as much as 18 lb. Over the years the number of pins has varied between 3 and 17 but the normal number is 9 hence the alternative name of *Ninepins*, though in some parts of England 10 are still preferred.

English skittles using nine pins is played in an alley about 12 yards long and 3 or 4 yards wide. The pins are set up in diamond formation, and players throw the cheese at them from a distance of 6 or 8 yards being allowed one step forward during the throw. There are several methods of scoring. In one the object is to score 31 in as few throws as possible, each pin knocked down counting 1 and any throw in which more than the number still required are knocked down not counting. Another method is to knock down as many pins as possible in a fixed number of throws.

the highest total winning. Yet another allows each player three throws in each of a fixed number of turns, scoring being 3 if all nine pins are knocked down in one throw, 2 if in two throws, 1 if in three throws, and 0 if any are still standing after the three throws. Pins must be hit by the cheese direct or by another falling pin. Pins knocked down by rebounds do not count.

The Dutch introduced skittles as played with a round ball and nine pins to America in the 18th century. The game rapidly became popular but in 1841 it was made illegal because of the betting on it. However the law specifically mentioned nine pins so the organisers simply added a tenth and the game survived. As Bowling it became very popular in 1952 when a machine was invented for replacing the pins automatically and there are now over 30 million players in the United States.

In 1960 this form of the game reached Britain where it soon became easily the most popular version of skittles, there now being well over half a million players. There is a British Tenpin Bowling Association and a Tenpin Bowling Proprietors Association of Great Britain. The bowls some of them converted cinemas offer many of the facilities of a social club. Competent instructors are available at them, and there are countless competitions and leagues.

Softball. *See Baseball.*

Solo Whist.

Solo Whist is a card game for four players who normally act independently. Play is as at Whist (qv) but the cards are dealt in threes the final round being dealt singly and the dealer exposing his last card to indicate trumps.

Players then 'declare' in turn starting with the player on the dealer's left. The lowest call is I propose, which entails making eight tricks with a partner, any one of the other players being eligible to accept in his turn. The next call is Solo, which requires five tricks to be made unassisted. Next comes Misère in which every trick must be lost and then comes Abondance in which nine tricks must be made. Higher still is Misère Ouverte in which every trick must be lost with the player's hand exposed and highest of all is Abondance Déclarée in which every trick must be made. Any player may Pass, and once a call has been made, later callers must make a higher call or pass.

Though calls are made with trumps already nominated, certain calls may alter the trumps and, with regard to these, there are several views, all quite widely held as to the rules that should apply. A player calling Abondance can choose his own trumps though Abondance in the nominated trumps—called Royal Abondance—takes precedence over the same call in another suit. In Abondance one school of thought holds that the first round is played on the nominated trumps while another takes the view that the first card only is played on the nominated trumps. In either of these circumstances a player making this call should not announce his trumps until the round or card has been played, unless it is necessary to announce Royal Abondance to overcall. There is, however, a third view and it is the view of the majority of authorities who have actually written about the game that the new trumps should be announced before the hand starts. Also the subject of differing views is Abondance Déclarée, one view being that the caller can choose his own trumps, and another that in this call, there are no trumps, though both views agree that this call confers the right to lead. A good

player can easily adapt himself to any of these variations the important thing being to check which versions are being used before starting to play. On the Misère calls there are no trumps, and in Misère Ouverte the player need not expose his hand until the first round has been played.

Speed-Skating. *See Skating.*

Squash Rackets.

This game is played on the same principle as its forerunner Rackets (qv) but in a smaller court with a shorter racket and a rubber ball. It is mainly a singles game though doubles can be played.

The court has four walls with the rear part divided into two service courts each having a small service box down the court by the side wall. The server must have one foot in the box and serve the ball on to the front wall above the cut line (6 ft. in singles) so that it comes back diagonally into the other service court. But it need not land direct or land at all, but may strike the side wall or back wall or both and be volleyed by the receiver. The object of the game is to score points by striking the ball in such a way that the opponent is unable to return it or make a proper shot. Every shot played in a rally must hit the front wall (directly or via another wall) and must be played on the volley or after one bounce. The service ball must always hit the front wall first. Service proceeds from the two boxes alternately. It is important to note that unlike Lawn Tennis (qv) services that would be faults become good if taken by the receiver. A game is 9 points but if 8-8 is reached the winner is the next to score 2 consecutive points. Only the server scores points winning shots by the receiver entitling him to take over the service. Players sometimes accidentally impede each other and when this happens it is a let and the point is replayed.

The game enjoys great and increasing popularity. The Central Council of Physical Recreation co-operates with the Squash Rackets Association (the game's governing body) in running courses and there are coaches at many clubs. Though many people play purely for exercise and enjoyment there are many competitive events, both national and international. Internationally Squash Rackets is largely dominated by the Egyptians and Pakistanis but a rapid rise in popularity comparable with that in Britain, has brought Australia very close to the top. The game has developed along slightly different lines in the United States but with the growth of international competition and the formation of an International Federation the differences from the standard game are likely to disappear.

Surf Riding. *See Swimming.*

Swimming

Swimming is an extremely popular pastime that also shares with walking the distinction of being a perfect exercise for health as it exercises the whole body and can be carried out as easily or as strenuously as the swimmer wishes. It is also a very useful accomplishment that may at any time put its possessor in a position to save a life.

There are several different swimming strokes, the basic stroke being the breast-stroke, now often seen in an alternative method, the butterfly. Faster strokes include the side arm, the overarm, the trudgeon, and the crawl, but each of these attempts to speed up progress through the water has really superseded its predecessor and the crawl is now almost universal. There are also

two strokes used in swimming on the back, one being a back equivalent of the breast stroke and the other a back crawl. It is possible to swim under the water using the breast stroke and to keep the eyes open while doing so. It is also possible to swim down through the water to retrieve objects that may have been dropped. Ascending through the water is automatic though it can be hastened by a kick. Remaining stationary in deep water can be achieved either by floating on the back or by leading water which simply means moving the legs gently up and down.

It is not difficult to teach oneself to swim and like cycling it is an accomplishment which once learned is never forgotten. The main thing is confidence or an absence of any fear of the water. Such fears are quite unnecessary for water is an element that always tends to keep a human being on the surface and not to draw him under. Going underneath the water and staying under neath requires a definite physical effort and if that effort ceases the swimmer is automatically brought to the surface again. Many non-swimmers who get into difficulties increase these by struggling wildly for by doing so they may easily take and keep themselves under. If they would make only the gentle movements of treading water they would both stay afloat much longer and present far fewer problems to any swimmer who might be trying to save them.

Saving life in the water is the object of the Royal Life Saving Society which teaches the best methods of bringing people who are in difficulties ashore and also methods of artificial respiration for use in reviving the apparently drowned. Every swimmer should acquire some knowledge of life saving for even a strong swimmer may experience considerable difficulty in saving anyone unless he or she has some idea of the best way of setting about it. Many swimmers for instance normally use only the crawl and the back crawl whereas to save anyone it is almost essential to use either the breast stroke or its back equivalent.

Swimming has a well-organised competitive side with many competitions and championships right up to the Olympic Games. Most races take place in baths but there are some river and sea events and the greatest competitive challenge to any swimmer is of course the English Channel. Although this has been conquered many times the swimming of it remains, and will always remain a wonderful achievement.

Diving Generally accepted as being akin to swimming though actually it is quite a different sport is diving. Competition diving means using boards of various heights performing certain set dives and choosing additional ones from an approved list. Diving requires a certain amount of nerve and also gymnastic ability including the ability to control the body in the air. Whereas strong swimmers are generally fairly big divers are often much smaller and more compactly built.

Water Polo In view of the popularity of swimming it is not surprising that there is a water team game thus being water polo in which the object is the scoring of goals the ball and the goals resembling those used in soccer though all shots and passes are of course thrown. Throughout a history of nearly eighty years water polo has been beset by rule trouble and has probably been the subject of more codes of rules than almost any other game. The difficulty is the detection of fouls under the water the ideal a game of the basketball type free of bodily contact.

Surf Riding Though straightforward swimming, diving and water polo are the chief competitive water sports there are other water activities with large and in some cases, growing followings some of them also having their competitive side. Fairly old established is the

Hawaiian sport of surf riding which has been seen though generally in a rather milder form in many parts of the world. It consists of placing a flat board on the water and then lying or more rarely kneeling or standing on it and being carried ashore on the crest of a wave.

Underwater Swimming Undoubtedly the fastest growing of all swimming activities is underwater swimming which is a link between ordinary diving and swimming under water with the swimmer depending on his own lungs able to remain below for only a few seconds and fully fledged deep sea diving with the diver weighed down with equipment and receiving assistance from the surface. The underwater swimmer receives no surface assistance but he does use light equipment consisting of an artificial lung and breathing tubes and also a mask and flippers. This type of swimming developed during the Second World War in which Naval underwater swimmers called frogmen rendered great services. Frogmen can also render useful services in peacetime in for instance the sometimes necessary searching of rivers and canals in underwater photography and in exploring wrecks and even old lost cities now under water. There is also a vast amount of knowledge excitement and pleasure to be gained from a close up study of the many fascinating aspects of the underwater world.

It might be thought that the first step towards becoming an underwater expert was to become an expert swimmer but it is not essential for an underwater swimmer to be a surface swimmer of anything like championship class. There are of course dangers and the newcomer to underwater swimming should not go down too deep until he has had a good deal of practice and gained a certain amount of experience. Preferably the first descents to any depth should not be under taken alone and if the swimmer has gone at all deep he should come up slowly otherwise he risks getting the bends which is a serious disease and means that reduced air pressure has caused nitrogen bubbles to form in the tissues. There may also be danger from large fish and under water swimmers should not venture into undersea caverns without a light. It is always advisable to collect as much local information as possible before diving in a strange area. Though all kinds of equipment including cameras harpoons knives and torches can be carried the beginner will make a better start if he dives without encumbrances. Most of the dangers can be avoided or circumvented with care and the reward for those who master underwater swimming is a whole new world to explore.

Table Tennis

Originally simply an amusing parlour game known as Ping Pong table tennis is now a serious world wide competitive sport with many championships and tournaments and is played on an organised basis by more than 7½ million people in all the continents.

Resembling a miniature game of lawn tennis (qv) the net is set on a table 9 feet long by 5 feet wide and the ball is a very light celluloid one. Players serve series of five balls in turn both server and receiver scoring. The service has to bounce first on the server's side of the net and then on the other and thereafter all strokes are ground strokes volleying not being allowed. A game is 21 points and matches are usually the best two out of three or three out of five games. Vantage games are played as if the score reaches 20 all each player serves once in turn until one has a clear lead of two points. Both singles and doubles are played.

The English Table Tennis Association state that from September to May each year over 10,000 individual matches are played each evening in England.

Traditional Games and Customs.

Traditional and unusual sporting events are plentiful in many parts of the world but few have a longer tradition behind them than the *caccio* that can still be seen in Florence. It is a version of football based on an ancient Greek game called *epheuros* and the old Roman game of *harpastum*. Played twenty seven a side on a pitch rather smaller than an Association football pitch it was originally restricted to the nobility and in 1673 a game was cancelled when it was discovered that the selected teams included players who were only gentlemen. The ordinary people did play but the game as played by them was called *calcio diviso* and was not regarded as the same thing. The playing of *calcio* in Livrea faded out in 1739 but was revived in 1898 to stop again in 1902 only to be revived once more in 1930. To day there are generally two games a year between teams no longer restricted to the nobility and representing the four quarters of Florence. They are wonderful spectacles for the players and also numerous officials and attendants wear fourteenth-century costume and the games are preceded by ceremonial processions and by a special address to the most distinguished person present. The trophy for the games is traditionally a white calf.

Another ancient Italian sporting event that still survives is found in Siena and consists of horse racing in the city. It is a wild and fierce form of racing in which virtually anything that might further the cause of victory goes on between the riders. Riding events many of them of great antiquity figure prominently in countries in which great horsemanship is an age old tradition. Russia offers *kop karri*, a fifteen a side mounted game that is a battle for possession of a sheep's pelt. Riders carry their reins in their teeth to leave their hands free for the fight and anyone who gets the pelt is soon downed in what is one of the roughest and toughest games of all time. Played now by Kazakhs from the Steppes and Tadzhiks from the Afghanistan border this game originated in China and was brought out of that country by the riders of the Golden Hordes of Genghis Khan. Also found in Russia is the mounted kissing game in which a galloping male horseman seeks to snatch a kiss from a girl rider armed with a whip.

Horses are also prominent in North American Rodeos which consist of competitions in cowboy skills such as riding roping steer wrestling and chuck wagon racing, which can still be seen annually in rodeos like the famous Stampede at Calgary in Alberta. Rather different are Chilean rodeos which consist mainly of displays in vying horses and young bulls and the *tope adura*, in which two mounted teams push against a long log suspended horizontally between them. Chilean rodeos carefully avoid anything that might harm the animals which enter into things with excitement and enjoyment. This also applies to the bull races at *Pamaksan* in the Indonesian island of Madura. Based on the local method of plunging these consist of races in which a driver stands barefooted on a small wooden sled harnessed to a pair of bulls though these need little driving. In India elephant racing may be as much as a thousand years old, but it is now being allowed to decline because of reputed feudal associations. Recently there was a not-very-serious attempt to introduce it into the United States, which is, however, more at home with events like Florida's Swamp Buggy Derby in which vehicles carrying two hunters and their equipment must cover a figure eight course of a mile within ten minutes.

Differing widely from these events in every thing but speed is *pelota* or *jai alai*. Played in Spain France Portugal, North Africa and South

and Central America, *pelota* is a traditional Basque game that developed from a medieval form of handball that was played against village church walls. To this day many *pelota* courts called *canchas* are next to churches the wall, or fronton which is an integral part of the game being that of the church and the priest very often being one of the best of the local players. The game which is very fast and exhausting can be between two players or between teams of two or three and consists of playing a ball that is rather smaller than a tennis ball against a wall with either the hand or in the case of the most popular form of the game the Grand Chistera with a long narrow wicker basket called a *chistera* that is strapped to the player's hand and arm.

Personal combat sports have always been popular and Switzerland has a national sport of this type that had its first big tournament in 1905 in *Das Schwingen* which means The Swinging. It is a form of wrestling, in which the contestants normally very powerful Alpine herdsmen wear special belts and shorts by which holds are taken. The traditional prize for the winner of the annual Swiss championship is a two-year-old heifer. Iceland has a rather similar form of wrestling called *glima*. Much less similar is the Siamese form of boxing. Competitors in this wear and use ordinary boxing gloves but they are also allowed to use their elbows knees and feet which are bare.

Next a group of recreations in which the feet are used less lethally starting with the Netherlands and the Nijmegen Marches. Over half a century old these are international long-distance walks that are not races but reliability trials in which complete teams must start and finish together within a certain time. The marches take four days, the distance to be covered each day varying between 25 and 80 miles according to the class. Classes catered for include men, women and also police teams walking in uniform and military teams carrying equipment. The walks which attract over 10 000 competitors every July are an unusual and colourful spectacle and the opening ceremony is as well worth watching as that of the Olympic Games. British walkers, civilian, police and military regularly take part. Though called marches they are really walks, and it is unlikely that many men would consider real precision marching as a recreation. However women do in at least one country. This is New Zealand where marching competitions are held between teams of twelve, with a leader each team wearing a special uniform and carrying out a three minute routine to the music of a pipe band. Points are awarded not only for the marching, but also for the costumes and the leading. Though the competitions are confined to women, teams are generally trained and drilled by men. This type of marching was seen in Britain a few years ago when the Blair Atholl team toured the country giving demonstrations.

Non English recreations that English people do not have to travel very far to see are the many and various activities that go to make up Scotland's Highland Games. Highland Games meetings, or gatherings, are sports meetings but sports meetings with their own definite and extremely colourful and spectacular characteristics. The chief sporting events at them are the heavy-weight events, including tossing the caber throwing the hammer in the Scots style putting and throwing weights of various sizes and wrestling. In addition, there are competitions in Highland dancing and piping and often for pipe bands, all playing their parts in a spectacle that can hold its own with any of the many spectacular events that love of tradition and love of sport have combined to produce all over the world. (See also Old English Games and Customs.)

Trampoline. See Gymnastics

Tug-of-War.

A Tug-of War is one of the least complicated and one of the most strenuous events in sport.

It consists of eight men pulling on a rope against another set of eight pulling in the opposite direction each team trying to pull the other forward across a line and each helped by a coach who instructs them when to heave and when to concentrate on resisting the opponents heaves. A pull may be over in a few seconds or it may take many minutes. Contests are generally the best two out of three pulls and a competition may involve three such contests in one afternoon. Competitions may be at catchweights which means that there is no weight limit or they may restrict the eight men to a total weight of say 104 stone or 100 stone. The tug of war requires and will help to develop great strength.

A popular event that always arouses great enthusiasm amongst the spectators the tug of war fully merits this position but it owes some of its success to the fact that it was introduced into the right place at the right time. In the nineteenth century before athletic sports were really organised most country sports meetings included events like obstacle races sack races and egg and spoon races. These however though they are found to this day in some children's and local sports grew less popular and began to give place to more serious ones a favourite replacement for them being the tug of war. Then athletic sports became organised and the Amateur Athletic Association was founded and instituted its famous annual championships including two Tug of war championships that still exist where a few years earlier there might have been obstacle race and sack race championships.

For years service units and police forces provided the leading tug of war teams but more recently they have been challenged by teams from big firms. A still later development has been the formation of clubs concentrating entirely on the tug of war. Organisations and clubs with tug of war teams now have their own association and their own annual championship meeting.

Underwater Swimming See Swimming

Underwater Watching

In recent years there has been a considerable increase of interest in the undersea world and some participation in this has been brought within the reach of those who are unwilling or unable to take part in underwater swimming and diving by the use of glass bottomed boats often boats in which the viewer slides back a wooden panel at his feet to reveal the glass viewing panel. Such boats of course can only be of use where the water is exceptionally clear and transparent but where conditions are suitable a surprising amount of the life and colour of the world beneath the seas can be seen and without any of the strain or danger of diving.

Much of the Mediterranean Sea fulfils the necessary conditions of clarity and transparency particularly perhaps, the coasts of Corsica, Sardinia, Sicily and Italy itself. Greek and Egyptian waters are also clear as are the waters of the Spanish Costa Brava and the Balearic Islands. Going farther afield there are very transparent waters off parts of the Australian coast and of course in the West Indies.

Volleyball

Long-established in the United States and played also in some other countries volleyball is a comparatively recent arrival in Britain, where it has been encouraged by leading personalities from the sport of athletics, who saw in it an ideal game for maintaining fitness and formed a governing body to organise and control it. A league started in London owed much of its early success to players of nationalities other than British but the game took a big step forward when it was adopted by the London Fire Brigade as an effective method of physical training.

Volleyball might be compared with basketball (qv) in that it is a team game that can be played indoors though it can also be played on outdoor courts. The actual game however differs widely from basketball. Played six a side on a rectangular court that should not exceed 60 feet by 30 feet it consists of volleying an inflated ball across a net 8 feet high with the hands the object being to make it touch the ground in the opponents court while preventing it doing so in your own.

Water Polo See Swimming

Water Skiing

Water Skiing originated in the United States in the early nineteen twenties and actually descends from surf riding (qv). Surf riding led to Aquaplaning in which a board was towed by a motor boat with the rider standing. A further development saw the board giving place to actual skis and water skiing was born. It eventually reached France and then in 1950 Britain.

In Britain it rapidly became popular partly through television which demonstrated it when it was still in its infancy. This led directly to several new water skiing centres being opened up in various parts of the country. Britain now has over 75 000 water skiers and there are about a hundred clubs most of them affiliated to the British Water Ski Federation. The Federation which is second in size only to that of the United States is in turn affiliated to the World Water Ski Union.

Water skiing has been described as the ideal family recreation for though at the highest level it requires great skill and demands almost anyone including children can quite easily acquire sufficient skill to enjoy it as a recreation. The more ambitious can if they wish proceed to such variations as monoskiing using only one ski slalom when the skier generally on one ski is towed through a staggered arrangement of buoys jumping from a ramp between three and six feet high and tricks which vary from the quite simple to the very difficult. There are water ski championships both national and international these involve slalom jumping and tricks.

The Central Council of Physical Recreation holds water ski courses—most of them on Lake Windermere—and there are also coaches at many clubs. Water skiing can be practised in a swimming suit but many skiers wear special rubber suits or at least jackets.

Walking

Walking comes so naturally that few people ever think about it. It is however worth thinking about for it is the basis not only of everyday life but also of every physical recreation. It has been said that it is impossible to walk too much and while those who have done little walking would of course have to increase the distance gradually there is no doubt that a regular daily two or three mile walk would in itself prove an effective method of maintaining health and fitness.

A great deal of pleasure can be added to walking about the countryside by taking an interest in those things which will help you to understand the history of this island. The countryside is rich in churches historic buildings ruins wayside crosses prehistoric camps and dykes. Besides a good pair of shoes you need a pencil a notebook, a 1 in Ordnance Survey map a good guide book and a fund of optimism imagination and curiosity. During your rest intervals you can study the map and plan and read one or more of the many back ground books to supplement what you have seen and stimulate you to further adventure. Not only is our countryside full of interest it is remarkably varied. Among the organisations which provide rambling opportunities are the Ramblers Association the Holiday Fellowship and the Countrywide Holidays Association. See also Long-distance Routes Section L.

Weight-lifting

Weight lifting is a method of exercising to maintain health and develop strength a system of training that can usefully be at least a part of the preparation for almost any sport or game and a highly organised and very popular competitive sport in its own right. Once quite erroneously thought to be an over strenuous and dangerous activity it has now in more enlightened days seen the pendulum swing completely in the opposite direction with professional and amateur sportsmen of all kinds freely admitting how much they owe to it and a large following of seekers after health and fitness including women many of them actresses models and others whose work demands a near perfect figure.

When it is used as exercise and training the strenuousness of it depends entirely on the wishes of the lifter or his or her adviser for training with weights does not mean lifting as heavy a weight as possible but carrying out a certain number of repetitions in various styles with weights well within the lifter's capacity. For those keen to develop the maximum strength of which according to their build they are capable weight lifting is certainly the quickest and perhaps the only way of achieving this. One of the charges levelled against it is that it makes one slow but this is just another fallacy. It does not and competitive weight lifters actually make some of the fastest movements known in sport.

As a competitive sport Weight lifting is divided into weight classes and there are many international and national championships and competitions. The sport is popular almost all over the world and has been firmly established in Britain for many years.

Strand Pulling akin to weight lifting in that it is a method of keeping fit and developing strength that is also a competitive sport is Strand pulling using a steel or rubber expander. Various different pulls are possible and the strength and resistance of the expander can be altered at will. Many people use this old established system of exercising for health and strength and for those interested there are many strand pulling championships and competitions.

Whist

Whist might be called the standard card game. It has never excited quite the furore of Bridge (qv) but it is long established and popular both at home and at Whist Drives. It is probably the first card game apart perhaps from a few simple games depending on luck that most people learn and it provides a sound foundation for the embryo card player.

It is played by four people two partnerships of two opposing each other and with a normal pack of cards. The partners sit opposite each other and the pack is shuffled out for trumps and dealt out singly. The cards are then played out in thirteen tricks of four each the player on the dealer's left having first lead and the winner of each trick leading in the next. Ace counts as the highest card—except in cutting when it counts as the lowest—and it is followed by king queen knave and then on from ten downwards. The higher card of any suit takes the lower unless it is trumped by a player unable to follow suit the tricks being gathered up by the winner as made.

It is necessary to concentrate to watch the cards played and to endeavour to place the unplayed cards. This comes with experience as does an understanding of such unwritten rules as Second in hand plays low and Third in hand plays high and a knowledge of when to disregard these.

Three handed Whist is possible one suit being discarded.

Winter Sports

There are few fields of recreational or sporting activity to which given the opportunity British people take more eagerly than Winter Sports. Enthusiasts from Britain were going abroad to find and in some cases start them before the turn of the century and to day there are probably a hundred travellers for every one who went sixty years ago.

Switzerland is of course the traditional objective but there is actually a wide choice for facilities exist in Norway Austria Italy France Germany and Czechoslovakia. There are opportunities to suit most purses and to suit both those who want only sport and those who want sport combined with entertainment. If the object is simply Skiing the most popular of the winter sports there is really no need to travel further than Scotland which provides excellent facilities and is increasing these every year.

For those whose time and experience are both limited Skiing is normally of the downhill variety rather than the lengthy journeys on the level as well as on hills and up as well as down at which many Continental and particularly Scandinavian skiers are adept. Greatly increased facilities in the way of ski lifts enable the holiday skier to work in three times as many descents as the skier of only a few years ago. Almost every resort has a ski school with an English speaking instructor and it is always advisable for a novice to join this. It is also advisable for novices to start training for a ski holiday some time in advance both by ordinary physical training and by attending a dry ski school. The air in winter sports resorts encourages more activity than is good for a completely untrained person and the fitter the skier the less his chance of being injured. Skiing accidents are plentiful but many of them could be avoided by the exercise of a few simple precautions. Having lessons is one thing being fit is another. Short skis with safety bindings are still another and refusing to ski late which may be any time after four o'clock is yet another for as the light fades it is replaced by a bluish light that makes uneven patches difficult to see and the snow tends to ice over. Most winter sports equipment can be hired but hired or bought and regardless of the extent to which fashionable skiing clothing may be advertised the most important items are the boots. The winter sports season lasts from December until March but the snow is sometimes late and while Christmas and New Year should be safe enough February offers the certainty of snow combined with longer days.

Ski jumping is a separate sport and one for experts. The jumper takes-off down a steep slope and over a platform which he leaves at a speed of about 50 m.p.h. to land something like 150 feet below his take-off and more than that distance out in front of it. Ski jumping is really ski racing behind unriden horses but the term is also applied to quite gentle ski trips behind ridden horses horse drawn vehicles and mechanical vehicles.

The biathlon is a combination of skiing over a 20 kilometre course and rifle-shooting. There is a World Championship and Britain enters for this but the leading exponents of this sport are the Scandinavians and the Russians. As with the modern pentathlon (qv) most British competitors are servicemen, but the sport is in no way barred to civilians.

Bobsleigh riding and tobogganing consist of riding and racing down ice runs at terrific speeds on sleighs the bobsleigh being for two four or five riders and the toboggan, which takes its name not from anywhere in Europe but from a Red Indian language being for one rider. Bobsleigh crews sit, the first man steering by a wheel or ropes, and the last man operating the brake with which the sleigh is fitted. Toboggan riders lie face downwards and brake through special

spikes on their boots. Both sports are exceptionally thrilling and both can be dangerous.

Even greater speeds ranging from 50 to 100 m.p.h. and even greater danger are to be found in ice yachting. This sport or something very like it has actually been known for hundreds of years but it is now rarely available in Europe because of the lack of frozen lakes large enough for the modern high speed yachts. In the United States however there are over 3 000 such yachts to be seen during the season which as with European winter sports lasts from December until March. One man ice yachts normally carry about 75 square feet of sail but two man yachts may carry as much as 650 square feet.

At the opposite extreme from the point of view of speed is the 400 year old Scottish game of curling which is played on ice but not on skates. It resembles bowls (q.v.) but the implements used are curling stones weighing about 35 lb. and having handles. Slow but still moving stones are encouraged by sweeping the ice in front of them with brooms.

Not a European winter sport but nevertheless a snow sport in Canada is Snowshoe Running. Like skiing this is a useful method of travelling about on snow that has been made the subject of races. The Canadian side of the Atlantic is also the home of Snow Snakes. A Red Indian game that consists of throwing a polished wooden stick along an ice trough in the snow. These snakes have been known to go for over a mile and to travel at 120 m.p.h. (See also Skating.)

Wingfield Sculls See Boat Races

Wrestling

Wrestling an individual combat in which competitors using only their bare hands endeavour to throw each other is one of the most natural sports and also one of the oldest. It is practised in many countries and in many different styles in most of which the wrestlers are divided into classes by weight.

In Britain probably the most popular style is Catch As Catch Can in which the wrestlers start apart and may try to throw their opponents by grasping them with the hands or by various kinds of trip. During the bout the competitors may be either on their feet or down on the mat and the rules contain various provisions to prevent the bout lasting for an indefinite time. Wrestlers reaching a deadlock on the mat may be ordered to stand up and start again and points decisions after a certain time are also possible. Certain dangerous holds are barred.

Another style is Cumberland and Westmorland wrestling which is extremely popular in those counties and in Scotland. In this the wrestler clasps his hands together behind his opponent's back and all throwing is done by the legs the breaking of the opponent's clasp constituting the fall. The initial hold is therefore of major importance and the taking of it often takes longer than the actual bout.

A further form of British wrestling is Cornish wrestling in which the wrestlers wear canvas jackets by which all holds are taken. A similar form of wrestling is found in Brittany.

In Graeco Roman wrestling which has always been very popular on the Continent though less so in Britain wrestlers start apart and may take hold only above the waist. Bouts in this style may take a considerable time. At one time there were many Graeco Roman handicap matches in which a top-class wrestler undertook to win a fall, or a number of falls, in a fixed time.

Graeco Roman was formerly the style used in professional wrestling but in recent years professionals have used the Free or All In style. This has rules but it is not always very clear just what they are and this combined with widespread suspicions that bouts are not really genuine contests has led to the quite large following that it retains going to see it more as an amusing stunt than as a serious sporting event. All this has of course done considerable harm to the reputation of what is really a fine sport and a healthy exercise.

Judo Wrestling has been popular for centuries in Oriental countries such as India, China and Japan. Of the various styles one from Japan has won popularity in many countries including Britain.

This is Judo which derives from the more elaborate Ju Jitsu. Governed largely by rituals and with wrestlers graded according to ability Judo is now an international competitive sport but it is still often taken up as an effective method of defence against a stronger or better armed attacker. Requiring a knowledge of anatomy it consists partly of defence by knowing how to fall and partly of attack by locks which are the opponent's choice between capitulation and a broken bone and by paralysing nerve centres. The various locks are potentially dangerous and when practising should be released immediately the opponent requests this. Also developed in Japan though it originated in China is Karate a combat system so potentially dangerous that when practised as a sport attacking moves must only be indicated and never pressed home. There are also Kendo (two handed fencing) and Aikido and Karatedo both systems of fighting without weapons.

Yachting

The first recorded sailing contest was a race from Greenwich to Gravesend on 1 October 1661 between Charles II who won and his brother the Duke of York. In those days such contests generally took the form of manoeuvring for positions of advantage rather than straightforward racing for the Royal Navy also relied on sailing and every privately owned vessel was a potentially useful naval auxiliary a fact that emphasises the appropriateness of the right of England's most famous yacht club the Royal Yacht Squadron to fly the White Ensign. The club was founded as the Yacht Club in 1815 becoming the Royal Yacht Club in 1817 when the Prince Regent joined and taking its present name in 1832. In 1851 the club put up for competition a silver cup that has become the most famous trophy in yachting and one of the most famous in sport. In that year a schooner of the then famous New York pilot cutter type called the *America* sailed across the Atlantic to compete in a 53 mile race round the Isle of Wight for the new cup capturing the trophy which now bears her name.

None of the many challenges by yachtsmen from Great Britain, Canada and later Australia has been successful though America's *Resolute* was nearly beaten in 1920 by Sir Thomas Lipton's *Shamrock IV* which won the first two races and was first to cross the line in the third race only to lose on corrected time. In 1958 when Britain's *Scout* raced the *Columbia* the rule about sailing the Atlantic to make the challenge was waived.

Land and sand yachting governed in this country by the British Federation of Sand and Land Yacht Clubs 151 Highbury Road, East Lytham St. Anne's, Lancashire was started on the Belgian beaches in the 16th cent. The fascination of it is silent speed at 50 or 60 m.p.h. in a three wheeled single seat craft. Firm wide beaches and aerodromes are ideal for the practice of this sport.

DOMESTIC PETS

This section attempts to deal not with all the many hundreds of animals that may be kept as pets but only with those that are best suited to average homes in Great Britain. The maintenance of monkeys, squirrels, bats, mongooses and snakes while quite feasible to those with experience and facilities requires considerable time and—in some instances—expense. Those who contemplate such exotic pets should consult works of reference, study the methods adopted in zoological gardens and discuss the matter with experts. Even in the case of the more common animals the information provided in the following pages is to be regarded only as a beginning to be supplemented so far as possible by practical experience, discussions with more knowledgeable owners, and the study of more detailed writings.

Certain considerations are basic. Never keep a pet unless you are really interested in it and are prepared to give it due—and regular—care and attention. Don't keep a pet you cannot afford to maintain in health and comfort. Scrupulous attention to cleanliness is essential and wise feeding is one of the most important factors in avoiding illness and loss of condition.

Since the passing of the Veterinary Surgeons Act of 1948 it is illegal for anyone to practise the diagnosis and treatment of animal diseases unless he or she is (1) a veterinary surgeon or (2) a person whose name has been placed on the Supplementary Veterinary Register. (Certain employees of Animal Welfare Societies are specially licensed but it is intended that in future all animal treatment shall be given by or under the direct supervision of members of the veterinary profession.) Not even a pharmacist may attempt to diagnose or treat an animal. Anyone may of course render first aid and an owner may—at his or her own risk—apply treatment. It is of course a wise precaution to seek veterinary advice for any ailing animal and the sooner it is sought the more likely it is that good results will follow.

BREEDS AND VARIETIES OF DOGS

Of recent years dog breeding and showing have become specialised occupations which average people cannot be expected to take up without having adequate time or resources at their disposal. Any amateur who wishes to breed for profit from pedigree animals should seek expert advice before attempting to do so.

Dogs which are intended for shows or for pedigree breeding must be registered in the name of the owner with the Kennel Club, 1-4 Clarges Street, Piccadilly, London W 1.

The following are the breeds of dogs recognised by the Kennel Club for the purpose of separate Registration and Stud Book entries—

SPORTING BREEDS

Hound Group

Afghan Hounds	Dachshunds (Wire haired)
Basenjis	Dachshunds (Miniature)
Basset Hounds	(Wire haired)
Beagles	Deerhounds
Bloodhounds	Borzoi
Borzoi	Elkhounds
Dachshunds (Long haired)	Finnish Spitz
Dachshunds (Miniature)	Foxhounds
(Long haired)	Greyhounds
Dachshunds (Smooth)	Irish Wolfhounds
Dachshunds (Miniature)	Rhodesian Ridgebacks
(Smooth)	Salskis
	Whippets

Gun dog Group

English Setters	Spaniels (Clumber)
Gordon Setters	Spaniels (Cocker)
Irish Setters	American
Pointers	Spaniels (Cocker)
German Short haired	Spaniels (Field)
Pointers	Spaniels (Irish Water)
Retrievers (Curly Coated)	Spaniels (Springer)
Retrievers (Flat Coated)	English
Retrievers (Golden)	Spaniels (Springer)
Retrievers (Labrador)	Welsh
	Spaniels (Sussex)
	Weimaraners

Terrier Group

Airedale Terriers	Kerry Blue Terriers
Australian Terriers	Lakeland Terriers
Bedlington Terriers	Manchester Terriers
Border Terriers	Norfolk Terriers
Bull Terriers	Norwich Terriers
Bull Terriers (Miniature)	Scottish Terriers
Cairn Terriers	Sealyham Terriers
Dandie Dimont Terriers	Skye Terriers
Fox Terriers (Smooth)	Staffordshire Bull Terriers
Fox Terriers (Wire)	Welsh Terriers
Irish Terriers	West Highland White Terriers

NON SPORTING BREEDS

Utility Group

Boston Terriers	Schipperkes
Bulldogs	Schnauzers
Chow Chows	Miniature Schnauzers
Dalmatians	Shih Tzus
French Bulldogs	Tibetan Apso
Keeshonds	Tibetan Spaniels
Poodles	Tibetan Terriers

Working Group

Alsataans (German Shepherd Dogs)	Poodles (Standard)
Bearded Collies	Poodles (Miniature)
Boston Terriers	Poodles (Toy)
Boxers	Pyrenean Mountain Dogs
Bulldogs	Rottweilers
Bullmastiffs	St Bernards
Chow Chows	Samoyeds
Collies (Rough)	Schipperkes
Collies (Smooth)	Schnauzers
Dalmatians	Schnauzers (Miniature)
Dobermanns	Shetland Sheepdogs
French Bulldogs	Shih Tzus
Great Danes	Tibetan Apso
Keeshonds	Tibetan Spaniels
Mastiffs	Tibetan Terriers
Newfoundlands	Welsh Corgis (Cardigan)
Norwegian Buhunds	Welsh Corgis (Pembroke)
Old English Sheep Dogs	

Toy Group

Chihuahua (Long coat)	Cavalier King Charles Spaniels
Chihuahua (Smooth coat)	Maltese
English Toy Terriers (Black and Tan)	Miniature Pinschers
Ciriffons Bruxellois	Papillons
Italian Greyhounds	Pekingese
Japanese King Charles Spaniels	Pomeranians
	Pugs
	Yorkshire Terrier

A separate register called a Breed Register is kept by the Kennel Club for each of the above breeds or variety of breeds. A separate register is also kept for the following —

Setters (Crossbred)	Spaniels (Interbred)
Retrievers (Interbred)	Spaniels (Crossbred)
Retrievers (Crossbred)	

A dog which is not eligible for entry in any of the above registers may be entered in one of the following registers kept by the Kennel Club —

Any Other Variety Interbred Dogs	Crossbred Dogs
----------------------------------	----------------

The following breeds among others are eligible for entry in the Any Other Variety register —

Alaskan Malamut	Japanese Akita
Australian Kelpie	Maremma (Italian Sheepdogs)
Bovier Belge de Flanders	Mexican Hairless
Dachbracke	Pedengo Ibicenco
Groenendaels	Polish Sheepdogs
Hungarian Kavasaz	Soft coated Wheaten Terriers
Hungarian Vislas	Tibetan Mastiff
Husky	
Iceland Dog	

Any dog will be accepted for registration in the Obedience and Working Trials Record irrespective of its ancestry on condition that it competes only in Obedience Tests and/or Working Trials.

Challenge Certificates are issued by the Kennel Club to certain Championship Shows for each breed or variety of a breed of which a separate register is kept. A dog qualifies for the title of Champion when it has won three Challenge Certificates under three different Judges.

In the limited space available it is impossible to describe the special characteristics of the different breeds. The breeds recognised in Great Britain are subject to constant review by the Kennel Club and it is probable that the number will continue to be added to from time to time.

The dog was probably the first animal to be domesticated in the true sense of the word and the uses to which he has been put by man are almost legion. Throughout the world dogs are employed to help protect herds and flocks and indeed the dog trained for shepherding plays an integral part in sheep management. The names Foxhound, Deerhound and Otterhound all indicate the specific uses to which dogs have been put in the Chase. Greyhounds and Whippets are used in coursing and work singly or in pairs rather than in packs. As their names indicate the various Setters and Pointers are employed to indicate the exact whereabouts of game and Spaniels also are widely used as gun dogs. The other uses to which dogs have been put in field sports include hunting over rough and difficult country by small terriers and going to earth to kill or hold badgers foxes and otters. Fox Terriers, Dachshunds, Dandie Dinmonts and Scottish Terriers are among the types which have been so employed. Dogs have played their part also in entertainment, thus there are performing dogs notably the Poodle and racing Whippets and Greyhounds while in former times various types of fighting including the baiting of bulls by Bull dogs were to be seen. The use of sledge dogs is well known while in Belgium and elsewhere dogs were at one time widely used as traction animals. In coaching days the Dalmatian was a carriage dog and modern scientists have recently suggested as a result of experiments that the position under or behind a coach which a Dalmatian automatically takes is determined by heredity! Perhaps the most exacting use to which man has ever put dog was in China where the Chow Chow was once maintained as a source of meat and fur! In Portugal fishermen employ a race of dog to accompany their fleets. The dogs in question (Portuguese Water Dogs) will dive into the sea to retrieve a broken net or an escaped fish and will even swim from one smack to another to convey messages! In New Guinea native dogs act as scavengers while in various countries on the Continent of Europe truffle dogs are employed to locate the fungi known as truffles relished as a table delicacy.

For present purposes it is however as a pet or companion that we are considering the dog and it must be agreed that many of the most successful animals for this purpose are cross breeds or mongrels. There are many fallacies or unsubstantiated generalisations regarding the relative merits of pure breeds and mongrels. This is in fact an intricate scientific problem and probably the simplest way of summarising the true position would be to say that from the point of view of health and temperament there are good bred and indifferent specimens among pure bred and cross bred animals. It is true that within a breed (or within a local community of mongrels for that matter) certain weaknesses or undesirable traits may arise from hereditary defects.

It may be noted that the word dog is applied to the whole species although it is used also to denote the male as opposed to the female for which the correct term is bitch. Young animals are referred to as dog puppies or bitch puppies respectively. A male animal employed regularly for breeding is known as a stud dog and the corresponding female as a brood bitch. In hunting circles the Foxhound is referred to as a hound and the term dog and bitch are employed only as prefixes to denote the sex.

CHOICE OF DOG

However attractive the idea of keeping a dog may be it is unwise and unkind to purchase or to accept one without very careful consideration. Dogs require regular feeding, grooming and exercise and if they are to be allowed to show their full capabilities constant companionship and attention. Nothing is more pathetic than the unwanted dog, which may have been purchased because of a passing whim and with which no one appears to have the courage to part. If on the other hand one is prepared to give all the necessary time and trouble to the proper care of the dog the reward will be ample.

The size of the choice is important. Many people keep dogs which are far too large for their houses and for their purses. The smaller the dog the less food, exercise, and house room will be needed and the many varieties of terrier provide a range from which suitable choices for most households may be made. In any event a very large dog should not be chosen unless expert advice has been taken about his feeding and other requirements.

Household dogs of six months of age or over must be licensed. Licences may be obtained from any post office (7s. 6d. at present).

MANAGEMENT OF THE DOG

Accommodation.—Up till comparatively recently most dogs were kennelled down out of doors. This practice has its advantages but to day the majority of pet dogs are allowed more or less the run of the house. A warm sleeping place such as a box or basket should be provided and should contain removable bedding. Newspaper is an excellent non-conductor of heat. It is a very useful material to place at the bottom of a dog's box and on two or three thicknesses may be placed a rug or blanket on which the animal may lie. It is astonishing the amount of dirt and dust a dog can bring into a house on his limbs and the lower part of his body. His bedding will require frequent shaking out and renewal and paper is easily changed. The box or basket in which the

dog lies should be allowed a place free from draughts and requires airing daily when the dog leaves its bed in the morning. Wood wool makes excellent bedding in outhouses or where a special structure is provided by way of dog kennel but is inclined to be messy about the house as a dog will draw portions of it about the room as he leaves his bed. If straw is used it is best stuffed into a sack and made into a kind of mattress. An odd piece of holeum forms an excellent foundation to the dog's sleeping box or kennel. It does not strike cold to the skin is a slow conductor of heat and has the advantage of being easily kept clean particularly during illness when there may be discharges and messes to be frequently cleaned up until the animal can once more go out of doors.

Exercise—Every dog should be exercised regularly but there is no need to over exercise and the practice of allowing a dog (other than a large and athletic animal) to run behind a bicycle for miles after miles cannot be too strongly deprecated. Two or three fairly short walks a day are sufficient for a small terrier always provided that there is a garden in which he can play on fine days and some open space where he can run freely for a short time. While still in the puppyhood stages a dog should be trained to walk to heel and to beware of traffic. Even so it is usually safer to put him on a lead in busy thoroughfares. One point which to the annoyance of the public many dog owners fail to realise is that their animals would show much less tendency to fight if allowed to investigate one another off the lead. A dog naturally feels aggressive if put on the lead immediately a rival hails in sight. There are of course certain dogs which attack others at sight these are a public nuisance and should never be allowed loose on the streets.

The practice of allowing a dog to take his own exercise is to be deprecated especially in towns and suburbs. The animal will be tempted to sniff into dustbins and if a male will tend to follow a bitch in season or to take part in the unsavoury dog parties which are so often to be seen. Further more such an animal is usually responsible for the disgusting habit of fouling the pavements and gateways. In this connection it should be emphasised that dogs may quite easily be trained to defecate in the gutter or on the grass verge and so avoid contamination of the pavement or carriage way. In some districts owners are liable to a fine if their dogs foul the pavement.

Training—Patience combined with the gift of putting yourself in the dog's place is the chief requisite for successful education. It is most important to encourage regularity of habit as an animal will obviously learn very much more quickly if his daily walks and grooming take place at fairly constant times. A quiet firmness is the ideal method and a puppy should learn early that a command is a command and must be obeyed. There is no need to shout and make an exhibition of oneself or to race in circles after a disobedient puppy if these things are done the animal will never become so well trained as it otherwise would. Again it is rather ridiculous to chastise a puppy after he has somewhat belatedly decided to come to heel quite obviously he will then be liable to think that he has done wrong in actually coming to heel. Whatever happens it must never be that the dog becomes master there is no more unbecoming sight than that of a person with a frankly disobedient dog and if the animal be large and powerful it may prove a menace to its owner and to the public.

Puppies should be house trained at an early stage. If care and thought are given to the matter the animal will soon learn not to make messes in the house. However it is very stupid to forget all about a puppy or dog for many hours and then, out of sheer vexation chastise it for having made a mess. If puppies are let out every two hours or so at first they will soon learn not to make a mess. Encourage them for performing in the right place rather than scold them for doing so in the wrong one. Physical punishment should be administered only where strictly necessary and then in a sensible fashion. The most effective

method is to grasp the dog or puppy by the skin of its neck and to shake it.

Grooming and Washing—Whilst short haired breeds need little or no attention to the coat bar an occasional brisk rub down with a brush or rough towel (which incidentally puts a pleasant gloss on the smooth haired breeds) yet with the long haired breeds grooming should be carried out regularly and if the habit is made a daily one it will not be forgotten so readily. Nearly all dogs love this procedure and most dogs will actually ask for their daily groom by jumping on the table or bench on which it is carried out. Steel combs and brushes are sold by many shops principally corn chandlers though some store chemists also provide a suitable range of grooming kit for all breeds. There is a curious fetish current among many breeders that dogs should not be washed. There is no reason why with a few simple precautions a dog should not be washed whenever it is socially necessary. The first precaution is to use a soap that does not contain an excess of soda. The strong washing up soaps excellent as they are for certain purposes are too irritant for a dog's skin. While some of the toilet soaps suitable for human use may be employed for dogs the special dog soaps and shampoos are much better for the purpose. They are more suited to the dog's skin and coat and have better detergent properties. It is important not to have water that is too hot—as with a baby's bath it should be possible to dip the point of one's elbow into the water and find that it gives a pleasantly warm sensation but is easily bearable i.e. it should not be above 95-100° F. On emerging from a bath a dog will shake himself thoroughly and then if not curbed will roll on the floor or ground and speedily cover himself with dust or dirt! It is therefore necessary to give him a brisk rub down with old (but clean) towelling whereupon he may be allowed to dry off in a warm place free from draughts or in good weather put on a lead and taken for a brisk walk. In the case of many of the long-coated breeds it is customary to have them trimmed at the beginning of summer and this is a sensible precaution that may avoid a good deal of distress during hot weather. The smaller long haired dogs in particular such as Scottish Terriers suffer unduly from the heat if their coats are grown too long.

FEEDING OF THE DOG

Meat usually beef is generally regarded as the staple article of the dog's diet. It must be pointed out however that although the dog is naturally a carnivore (flesh eater) ordinary meat (muscle or flesh) is not a completely adequate diet and lacks certain factors which the wild dog would find in the blood bones liver and other organs of his prey. Furthermore it has been proved scientifically that dogs can thrive on a meatless diet. In spite of these reservations however meat must be regarded as an excellent article of food and if properly supplemented will prove very satisfactory. In recommendations which have recently been made in America (Dr S. R. Speelman of the U.S. Department of Agriculture) it is suggested that meat (beef lamb mutton or horseflesh providing that the last is fed regularly and not spasmodically) or meat substitutes (fish milk eggs etc.) should constitute one half of the daily ration and that the remainder should comprise approximately equal parts of cereal substances (bread biscuits) and of vegetables (carrots spinach onion beet etc.). It is pointed out that many dogs do not accept the vegetable material readily. On this basis the approximate quantities of food required by adult dogs have been calculated as follows—

Weight of dog	Total food per day
1 lb	2 oz.
10 lb	12 oz.
25 lb	1½ lb
50 lb	2 lb
75 lb	3½ lb
100 lb	4½ lb
150 lb	6½ lb
225 lb	7 lb

(Weights of up to 10 lb would include the toy breeds 25 lb would correspond to a Fox Terrier, Airedale Terriers and Retrievers would fall into the 50-75 lb class and the larger weights would be those of the very big breeds such as the St Bernard.) The quantities given are of course an approximation and no more. Dogs which lead a very active life will require more while those which take little exercise or which tend to put on fat easily will require less. Common sense is necessary and great care must be taken not to over feed or to under nourish.

Meat is probably best fed raw or lightly cooked but many animals appear to have a preference (probably through habit) for well cooked meat. In any event the meat should not be over done as there is substantial evidence that prolonged heating destroys much of the food value of the meat protein. *Fish* is an excellent substitute. There need be no anxiety about the greed with which a dog swallows lumps of meat and also neglects to masticate them. The teeth of the dog are for tearing meat; he is not concerned with biting his food up small. Indeed his salivary glands contain no digestive ferments as is the case with some other animals.

Milk is almost essential during pregnancy and lactation (see below) and may well be included in normal diets. Whether or not bones should be fed is a matter which has been hotly debated but for mature household dogs the evidence suggests that they are unnecessary. (The teeth of racing greyhounds which receive a sloppy diet are quite as good as those of the average household dog.) Bone feeding is responsible for much trouble including constipation, actual impaction of the rectum and lodgement of pieces of bone in the mouth or throat. The value of bones is of course that they contain large quantities of essential mineral substances and for this reason the inclusion in the diet of bone meal or of steamed bone flour or preferably a mineral supplement is recommended. Only very small quantities of these substances are required.

Bread is an article of food which is often overlooked in the case of the dog but there is no doubt that wholesome bread is very suitable indeed provided it is not fed to excess.

The answer to the question whether a dog requires vegetables is in the main no. From the Vitamin C standpoint they are quite unnecessary since it has been shown that a dog manufactures this vitamin for itself but the fact remains that many dogs particularly of the toy variety enjoy a few slices of banana or apple and there is no harm in letting them pander to their taste. Vegetables do help however to provide roughage and cooked (not raw) potatoes may be used in place of bread or biscuits. The dog—like many other animals—cannot digest raw starch properly.

Flaked maize and *oatmeal* are other substitutes but it must be remembered that the energy value of maize is high and that the dogs must never be overfed. *Dog biscuits* are an item that were long in disfavour with some professional people on account of their often having been made from agerised white flour (see section on Canine Hysteria) but now that this factor has been overcome and the biscuits themselves are being improved in other ways their use for the non meat portion of the diet may be recommended.

Clean fresh water must be provided at all times. In addition to the diets recommended above there are on the market several tinned dog foods which claim to be complete or almost complete diets for the dog. It must be said that many dogs (including those of the writer) have remained in excellent health when receiving one of these foods as a large part of the diet over long periods. There is therefore little that may be said against the widespread use of the better varieties of such products. Again it is a matter for common sense if an owner finds that his animal is thriving on such a diet he is wise to continue to use it.

It is customary to give dogs two meals a day. There is no need to give more than two to healthy adults for the dog's stomach is exceedingly capacious and adapted to long gaps between meals. Many dogs thrive on only one meal in twenty-four hours. Whatever plan is decided on, regularity should be adhered to and a meal or meals given at the same times every day.

Dogs require vitamins A and D and B complex. There are several ways of administering these but the special commercial preparations including the modern form of condition powder tablet are the most convenient.

The pregnant and lactating bitch require special consideration. The food requirements are very much increased in a bitch which is carrying puppies, especially towards the end of the period. Normally appetite is not a complete guide to a dog's food requirements but in pregnancy and lactation the bitch must not be allowed to go hungry. It is quite normal for a heavily pregnant bitch to require over one and a half times her normal amount of food and in lactation her requirements will increase still further. Milk is a most excellent article of diet at this time. Indeed there is no better way (apart from commercial preparations) of replacing the milk which the bitch is giving to her own puppies.

Up to the age of three weeks or so puppies need have mother's milk only but at any time after this it is a sound policy to give them additional food and so spare the mother and also render weaning (at from six to eight weeks) a gradual process. At first a little cow's milk or one of the commercial dog milk preparations may be given and gradually the puppies should be encouraged to eat solid food. Eggs (if they can be spared) wholemeal bread in milk, or even finely minced meat may be given at first in very small amounts but later in larger quantities. If this process is carefully carried out there will be far less trouble at and after weaning time. After weaning puppies should receive five or six meals a day and this number may be cut down gradually until two or three only are given to the fully grown dog. (The smaller breeds are fully grown at about a year.) More meat or meat substitutes and milk and less cereal or vegetable matter should be fed to the growing dog as compared with the adult. This fact is important as the substances present in meat and milk are required for laying down the growing tissues. Nevertheless the energy portion of the ration is important and the cereal or vegetable should be nutritious and not fibrous. It is possible to rear puppies by hand from birth if the bitch for any reason should die. It requires great patience for the first two or three weeks, as naturally the puppies will require feeding once or twice during the night. Special milks for puppies are to be recommended. Cow's milk requires enriching with fat and sugar to approximate to the composition of bitch's milk. Feeding will have to be done at every two or three hours and a very useful gadget is a fountain pen filler attached to cycle-valve tubing. Very small quantities are required for the first two or three days and a level teaspoonful of milk is more than sufficient for the average terrier at first. Even with the best care in the world hand fed puppies tend to be weaklings and do not grow as fast as those naturally fed. A foster bitch if obtainable is much to be preferred.

BREEDING OF DOGS

It is natural for adult dogs of both sexes to wish to breed, and in the case of the female especially it is an excellent thing if one can arrange for a suitable mating to take place. Bitches come into season or on heat" (lay terms for oestrus) at approximately six monthly intervals but it is not advisable to breed from the first season which occurs usually at about eight to nine months of age, but over a wide range of age according to breed and other factors. The periods of season often occur between January and March and in early Autumn, but there is no fixed rule. Each season lasts for three weeks. For the first seven days, approximately (pro-oestrus) a bitch does not permit mating though during this time she is a source of strong attraction to all males in the neighbourhood. At about the seventh to the tenth day the blood stained discharge, which tapers in the heat stage this is usually taken by the breeder as an indication that the bitch will stand to service. If possible, it is always better when puppies are wanted to allow mating to occur more than once. Under natural conditions a dog and bitch are usually strictly monogamous and mate for life and during the period

of oestrus will mate many times. A dog and bitch that are kept together all the time will probably behave naturally but under domestication both dogs and bitches usually become promiscuous. Many bitches will in fact accept service from different males on different days and the phenomenon of superfecundation i.e. the production of a litter that is fathered by two males may occur. It is therefore wise to retain strict control of the bitch throughout the whole of the three weeks or so she is in season. At the end of season the bitch passes into a state of metoestrus if she has not conceived.

If a bitch conceives she carries her puppies for a period of about nine weeks. There is however a normal variation of fifty eight to seventy days and puppies born before the fifty eighth day sometimes live. The number of puppies born varies with breed. In the smaller terriers it is usually from four to six but in Airedales and Alsatians the number may be eight to ten and the larger breeds tend to have even more offspring at a time. Birth usually takes place fairly easily in the larger breeds but there is often much difficulty in the case of the short-legged breeds such as Scottish and Sealyham Terriers, Pekingeses and Dachshunds. In some breeds in fact the problem is one that is giving serious concern to veterinary surgeons and breeders.

A short while before her puppies are due a bitch will make her bed. Owners are often amazed at the destruction of soft furnishings or even of wall paper that a previously well behaved bitch may carry out at this time. It is therefore by far the best to provide a suitable box (if the animal has not one already). A smooth floor such as a strip of linoleum serves for the bitch to give birth to her puppies. Her instinct to tear up everything given to her for bedding may lead to suffocation of the puppies by pieces of bedding. Provided labour occurs in a warm room it is sometimes better—according to the temperament of the bitch—to remove each puppy as it is born, placing a warm bottle underneath and bring it back to the mother when the last birth has occurred. At this time the bitch should be watched carefully for any discharge from the vulva or for any evidence of straining. If either of these occurs without results it is advisable to send for help as early as possible, especially in the case of the smaller breeds. Many hundreds of bitches are lost through neglect at this time and usually because it was not suspected that any thing was wrong. If the discharge becomes bloody or green, help should be obtained at once if no puppy is delivered. Similarly any great delay between births is a matter for concern. The afterbirth usually follows the puppy within a few minutes but puppies are sometimes delivered in their fetal membranes and in this case the latter should be gently but quickly removed. It is quite normal for the umbilical cord to remain attached to the puppy but the bitch will normally break it by biting through it.

The mother will wash and attend to the new born puppies and after the last is born it is a good idea to burn all the mess and to provide clean newspaper but do not worry or frighten the bitch more than is necessary. For the care and feeding of the bitch and her puppies see the sections on Management and Feeding. Puppies like kittens are born with their eyes closed but open them after about nine days—there again being considerable variation.

The phenomenon of pseudopregnancy is common in bitches and indeed to a minor degree it is probably present in most bitches following an oestrus without conception. In some bitches however presumably those with strong maternal drives the changes in the ovary may be accompanied by external signs of phantom or ghost pregnancy. These may include not only enlargement but actual functioning of the mammary glands and the making of a nest by the bitch just as if her puppies were really due. The average duration of pseudopregnancy is usually given as about two months and although variable it is often sufficiently near to the correct time after oestrus that everyone suspects the bitch to be truly pregnant. The condition may be suppressed with the aid of modern drugs but in some instances it is not realised that the condition is not real. In many cases only professional

advice can solve the mystery and radiographical examinations have often proved necessary to ascertain the truth, particularly in fat bitches of the heavier breeds. It might be well to note at this point that there is another condition of the older bitch that is known as *Piometra*. This condition usually reveals itself at the same time as the ghost pregnancy (and is sometimes a pathological extension of it) but is accompanied by considerable disturbance of health coupled in many instances with purulent discharge from the vagina. A bitch which is off colour in the weeks following pregnancy or which develops a discharge from the vulva (especially one which is dark in colour) may well be a *piometra* subject. The disease is most serious and often requires surgical intervention. As the best chance of success is to operate or otherwise deal with early a veterinary surgeon should be consulted immediately.

DISEASES AND INJURIES OF THE DOG

Canine Distemper and Para-distemper " (Including so-called Hard pad ")—It has long been recognised that the commonest and most serious disease of dogs throughout the world is canine distemper. Dogs of all ages and breeds are susceptible and no dog is free from the risk of infection unless it has recovered from the disease or has acquired an immunity for other reasons (see P8(2)). The disease is caused primarily by a minute agent known as a filterable virus (see P7(2)) which may be of varying type in that it will attack the body in different ways. Thus some strains of the virus are known as neurotropic because they show an affinity for the nervous system. Sometimes a dog will apparently recover from an attack of distemper only to succumb later to fits or other nervous manifestations due to permanent damage to the central nervous system by the virus. Often however the virus is not fatal in itself but will lower the dog's resistance and permit the entry or the activity of bacteria that may lead to pneumonia or other serious effects. These so-called secondary invaders as the bacteria are termed may prove as harmful as the original virus. Indeed once these bacteria have set to work it is too late to expect the best results from the use of serum and whether or not the dog will live through will depend upon the severity of the attack, the dog's power of resistance and good nursing. It is therefore most important either to prevent the disease by vaccination or to be able to send for veterinary attention (and hence for an injection of serum) immediately an attack is suspected. Any puppy which is listless or off its food or which may throw a fit or which is obviously unwell with other symptoms (e.g. cough or diarrhoea) may well be in the early stages of distemper and it is then (not the next day) that help should be sought. Many thousands of puppies (and older dogs) that have been injected with serum in the early stages of the disease have become perfectly normal within forty eight hours. On the other hand the number of dogs that die in Great Britain alone from distemper and distemper-like infections must assume enormous proportions. Distemper is a highly infectious disease and it is important that the owner of an infected animal should do his best to avoid contact with other dogs, ferrets or mink. Ferrets and mink are very susceptible to canine distemper. On the other hand human beings and cats are not susceptible to canine distemper and the so-called distemper of cats is quite a distinct disease.

A highly satisfactory means of vaccinating puppies against distemper was worked out about 1926-30 and this—named the Laidlaw-Dunkin—after its two inventors—has since afforded protection to thousands of animals. Modern vaccines are based on a virus which has been modified by growth on developing egg embryos or more recently in tissue culture. Puppies should be vaccinated when they are 10-12 weeks prior to this age the immunity induced by the vaccine may not develop satisfactorily. After vaccination the puppy requires some time possibly 2 weeks before an immunity is established. Sometimes vaccinated dogs suffer distemper or

distemper like signs due to secondary invaders causing disease on their own account or because they were already infected when vaccinated. Variants of distemper of which hard pad is an example may also overwhelm a vaccinated dog's immunity although this is uncommon with modern vaccines since several distemper strains are used in their production. Hyperimmune serum which is collected from animals previously hyperimmunised against distemper is available and can immediately aid the dog suffering from distemper but its effect is short lived (7-10 days).

Infectious Hepatitis or Rubarth's Disease—Another virus disease of dogs (and foxes) is known as Rubarth's disease after one of its discoverers now known as infectious hepatitis. This disease has been recognised in Sweden ever since the 1930s but in Great Britain only since the end of the war. The condition is extremely sudden in onset and an affected dog may be found dead. Many cases are however mild and in some instances only one or two out of a large group of dogs have been affected. The changes seen after death vary but the findings in the liver cells are usually characteristic. Specific treatment is not yet established as in the case of the distemper like conditions although the administration of antibiotics (see P8) may prevent the effects of secondary infection. An effective vaccine is now produced and often combined with the distemper chick embryo vaccine. A dog is thereby protected against both these diseases.

Canine Hysteria (called fright disease or running fits in the U.S.A.) is an alarming but not necessarily serious condition in that it can often be cured very readily which appears to arise from a variety of exciting causes. The affected animal rushes around wildly often screaming and howling and obviously loses all sense of whereabouts or ability to recognise people. After a more severe attack (and there are all degrees up to a full epileptiform fit) the dog may appear quite exhausted but returns to normal. Sometimes there are many attacks in one day. The dog will not wilfully attack people during a bout of hysteria—at least that has been the experience of the writer—but is very difficult to control. Apart from ensuring that the dog does itself no grievous bodily harm there is little that can be done until the attack has subsided. Then the animal should be kept as quiet as possible and given a tranquilliser.

Hysteria may be an hereditary taint derived from one or other parent. In certain circumstances however it may arise in apparently normal animals. There are several possible causes (including parasites) but a definite one is the bleaching agent—nitrogen trichloride or agene—employed for some years in the manufacture of flour and hence present in white bread and certain dog biscuits. Indeed the clear demonstration that agene could set up hysteria in dogs and subsequent scientific work has led to the introduction of regulations that have led to its abandonment as a bleaching agent in favour of other methods which have been found not to cause hysteria. There has already been a marked decline in the incidence of hysteria due to dietary factors.

Rabies is a fatal disease of dogs and is also due to a filterable virus. It is transmissible to the human being and to many other species but has fortunately been absent from Great Britain for many years. Stringent precautions are taken to prevent its entry and dogs which are brought into Great Britain must spend a long period in quarantine. A vaccine is available and people taking dogs to countries where rabies occurs should have their animals protected. Many countries insist on this procedure.

Tonsillitis appears quite frequently in dogs, and seems in many cases to be part of a more generalised infection. It demands expert treatment but although it may persist for a long time it usually yields to treatment.

Nephritis—Inflammation of the kidneys is unfortunately all too common in dogs, and in adult males in particular there is a high incidence of chronic kidney damage. One of the symptoms is a marked thirst. Sometimes this condition is a sequel to an infection known as *leptospirosis* which calls for prompt veterinary treatment if death or permanent damage is not to follow. It is always worth while seeking professional advice for a dog that drinks excessively or has a somewhat characteristic type of bad breath. A vaccine which gives a good immunity against the two common forms of *leptospirosis* is available.

Anal Glands which are found in the dog and in other carnivora often give rise to trouble. Animals which rub themselves along the ground are not necessarily affected with worms but with impaction of these two little glands which are situated one on each side of the anus. They secrete a peculiar dark coloured very offensive fluid which sometimes is not discharged properly and causes the animal great discomfort. The glands in such cases should be relieved periodically. Those who do not mind this somewhat dirty task may perhaps learn how to do it themselves. Occasionally segments of tapeworm are responsible for the impaction but usually the trouble has nothing to do with worms. Whenever a dog pays considerable attention to his anus this impaction should be suspected. Actual infection of the glands is also fairly common and demands expert attention.

Diseases of the Ear especially of the outer ear are very common in dogs. The dog's outer ear is somewhat more complicated than is our own and the drum is set more deeply. Hence it is easy for wax and dirt to accumulate for various parasites to establish themselves and for inflammatory conditions to result. The word *canker* (which has no precise scientific meaning) is sometimes applied by lay people to the more serious or chronic forms of inflammation of the outer ear canal. It is not difficult to diagnose ear trouble as the affected animal usually shakes its head or worries or scratches its ear and rubs it along the ground. The ears should be inspected regularly to see that there is no great accumulation of wax or dirt. Cotton wool twisted on to the end of a match stick or orange stick is quite satisfactory for cleaning out the ear providing care is taken. A dog which is continually worrying its ear or which has ears which are obviously diseased should not be neglected as the sooner expert treatment is begun the more readily will the condition be cured. Even if the lining of the ear is greatly thickened through inflammatory reaction and the lumen nearly occluded it is still possible for a plastic operation to be performed. Many hundreds of such cases have been successfully treated in this way. A percentage of inflammatory conditions of the outer ear is associated with ear mite infestation. In such an event treatment with modern anti mite preparations should be carried out.

Deafness in certain white dogs (e.g. in some Bull Terriers) appears to be hereditary and is quite incurable. Old dogs often become deaf and deafness has been produced experimentally in young puppies by feeding them on a deficient diet.

Diseases of the Eye are very common in dogs and are often the result of injury. Except for minor discharges from the corners of their eyes (and in younger dogs especially it must be ascertained that these are not a symptom of distemper) any eye disease is sufficiently serious to merit professional advice. Boracic lotion is not suitable for the eyes of dogs. It is slightly irritant and dogs are apt to scratch and make the eyes raw after application. Colloidal silver eye lotions and ointments are far more suitable pending the advice of a veterinary surgeon. In eye inflammation avoid sunlight and wind. For some days in the early stages of inflamed eyes the light in the room should be subdued. Pekinese seem to be especially

ally prone to eye disease but the remarkably unwholesome appearance of some affected eyes in this breed is not necessarily evidence that recovery is unlikely. Steps should be taken to ensure that the dog does not inflict further injury on an already diseased eye. Cat scratches are a frequent source of inflammatory conditions of the dog's eye. Eyes must never be neglected for the consequences are serious.

Skin Diseases are common in dogs and may be contagious. Among the common contagious causes of skin disease are lice, mange mites and fleas. Lice and mange mites (except for demodex) are killed by modern insecticides such as benzene hexachloride (gammexane) although two applications at a 10-14 day interval are required to destroy the young stages which are within the insecticide resistant eggs at the first dressing. The flea actually on the dog is only one of four stages in the life cycle of the flea; the others are in the house or on bedding. Insecticides used for flea control should therefore be applied every week or 10 days during the summer to kill the young fleas as they hatch and infest the dog. The dog's bedding should be discarded or cleaned. The dog also suffers from other skin diseases caused by systemic disorders for which expert attention is required.

Diseases of the Teeth and Gums are very common in household dogs. A serious systemic disease such as distemper may leave the enamel of the teeth permanently pitted; hence distemper teeth. More serious than this, however, is a form of pyorrhea which is really a disease of the gums rather than a primary disease of the teeth themselves. The margins of the gums become red and swollen and may bleed easily. As the condition progresses the teeth may become loosened. Particles of food become lodged between the teeth or between teeth and gums and add to the inflammation and to the smell of the breath.

This disease may if unchecked become very serious. In many cases extraction of one or more teeth is indicated but unfortunately it is not always possible to do this. The condition demands expert attention.

Another common condition of dogs' teeth is the deposition around them of tartar. This should be removed by scaling or by special use of dental forceps. Some breeders and others may themselves have learnt how to carry out these operations with the requisite skill and care, but they are not easy to the amateur and it is essential that no harm be done to the animal's soft tissues by injudicious use of the instruments. Ordinary dog owners are strongly advised to take their dogs to a veterinary surgeon in order to have the tartar removed.

Most puppies lose their first or milk teeth quite regularly between the ages of three and five months but sometimes there is difficulty and the primary teeth are not shed properly. These cases should be treated by a veterinary surgeon before the permanent teeth are thrown out of their proper alignment.

One hears very much about 'teething fits' in puppies and while these occur owners should be very careful to ensure that a 'teething fit' is not a sign of distemper which often starts with a fit. As puppies of this age are so susceptible to distemper it is advisable to seek professional advice should any form of fit occur. It may save much time, money and trouble and even the animal's life.

Internal Parasites 'Worms'—It is probable that more nonsense has been talked and written about worms in dogs than about any other canine subject. According to some people worms are the root of nearly all doggy evil, and so long as a dog is regularly wormed all will go well with him. These beliefs are frankly absurd. The real facts are very different and are stated in as brief a fashion as possible in the following sentences. In this country dogs are

infested by a species of roundworm (a creature which is a dirty white colour and in shape somewhat resembles the common earthworm) and by several species of tapeworm which are also whitish but which are flat and are made up of many small segments joined to a little head which is attached to the lining of the gut. In spite of all that is said tapeworms as such are rarely responsible for much harm to the dog although they can of course prove debilitating and should be removed. They are a nuisance and attempts to remove them should be made by administration of the appropriate drug. Occasionally segments of worm are responsible for impaction of the ducts of the anal glands (see above).

The roundworms may be extremely serious in young puppies in which they cause stunting, pot-belly, harshness of coat and dangerous or fatal illness. Fortunately modern anti-roundworm preparations are available for animals of this age. Once over the age of 4-8 months dogs rarely suffer serious illness from roundworms although these may cause occasional vomiting or even diarrhoea and some loss of coat and bodily condition. It is now known that puppies are infected before birth from their mother. It is therefore desirable to keep down the incidence of roundworms in the mother—and in dogs generally—and fortunately the modern preparations are—unlike some of the old-fashioned ones—safe in use and unlikely to cause digestive disturbances. From all that has been said above owners will realise the necessity of taking professional advice about young dogs which are ill and any signs of worms in young puppies—either in the stools or by some obvious intestinal upset or bloated appearance of the belly—should be acted upon. One last word about this aspect of worms—do not assume that your adult dog has tapeworms unless you see some evidence in his stools. There are so many signs of worms that veterinary surgeons must at times get a little tired of being assured that 'My dog has worms' because of some trivial habit connected with appetite.

There is however another side to the study of tapeworms and one which is not generally realised. The tapeworm which is found in the dog represents one stage in the life-cycle. The eggs which are present in the ripe segment passed by the dog develop not in the outside world but in another animal altogether. Thus one of the commonest tapeworms in this country has an intermediate stage as it is called in the flea and it is when the flea is eaten by the dog that this intermediate stage develops further to become a tapeworm. Another tapeworm has an intermediate stage which develops in the sheep and a third has one which develops in the ox. There is a fourth tapeworm which has an intermediate stage which may develop in man, to set up serious diseases in certain cases. Children may become infected through handling the dog and so picking up the eggs which may then be eaten through putting the hands in the mouth. The dogs which are most likely to be infested are those which have the opportunity to eat freshly killed sheep and other food animals. An ordinary household dog is not likely to be infested and people should not worry unduly in this connection provided they do not allow their dogs to stray into the wrong places. It is illegal to allow dogs to enter a slaughter house but unfortunately one often sees dogs in such places. The routine worming of dogs is justified if evidence of infection exists and certainly in country areas where opportunities of tapeworm re-infection may be plentiful.

Tumours, including malignant tumours ('cancers') are relatively very common in the dog—probably as common as in the human subject. Space does not permit of a detailed account but the following examples of growths may be mentioned: a proliferation of warts on the skin of puppies (usually disappear spontaneously); a true cancer of the tonsil in middle aged and older dogs of both sexes; cancer of the mammary glands in bitches (both incurable); fatty growths of the vagina of bitches (amenable to operation).

Space does not allow of the discussion of other

diseases but it should be pointed out that dogs are susceptible to human and bovine forms of *tuberculosis* especially the former. In a household which contains a tubercular person the dog should be watched for any signs of illness and the thought entertained that he might be responsible for the further spread of the disease. For a discussion on ringworm see the appropriate heading in the section on the cat (Z12).

Accidents and Injuries—In these days of swiftly moving motor transport street accidents to dogs are extremely common. Many could be prevented by training the animal to walk to heel by the use of a lead in busy thoroughfares, and by not allowing dogs to roam the streets unaccompanied—a thoroughly bad habit. Sometimes the victim escapes with a scare and a few bruises and at others death is mercifully swift. In the vast majority of accidents however a more or less serious injury is incurred and if the animal is unable to move the police should be notified immediately. The dog is best left quiet and it is not recommended that attempts be made to administer brandy or other supposed stimulants unless help is markedly delayed. Excessive hemorrhage may in some instances be prevented by common sense application of principles learnt in first aid courses.

One of the commonest accidents to dogs, especially to young dogs is a fracture involving the head of the femur or thigh bone. Inability to put one of the hind legs to the ground or to bear any weight on this limb is an indication of such an injury. (This injury may occur also from falling off a chair or wall.) Professional help is, of course required in such cases.

Cuts and Bruises if not serious may be treated at home as in the case of human beings. The indiscriminate use of tincture of iodine is not to be recommended and spirit alone makes a more satisfactory dressing in most cases. Simple washing and removal of dirt are usually sufficient combined perhaps with modern antiseptic ointments or other preparations. The dog (and also the cat) are very liable to sepsis and it is best in such cases to send for proper assistance early or there may be grave trouble. It is probable that in many of the flesh-eating animals and their lives as victims of the sepsis following wounds.

Injuries from cat-scratches are exceedingly common as are bites from other dogs. These are serious, as they more readily result in septic places. The scratch or bite sometimes penetrates quite deeply leaving a pocket which fills up with pus. This pus may spread under the skin to form abscesses. Never neglect such places.

Conclusion—There are a few concluding remarks on the treatment of the diseases of the dog—

(1) It is not correct that water should be withheld from a sick dog. It is true that an animal which is using water only to vomit or which is drinking excessively should have its water intake restricted, but it is wrong to deprive a dog altogether. It may be suffering from diabetes and should be taken to the vet for testing.

(2) There have been such wonderful advances in the field of veterinary anaesthetics that there is nowadays little to fear in this connection from operations to dogs and cats. The records over the past years at the Royal Veterinary College London and at other centres have been most encouraging and the anaesthetic risk is now small indeed.

(3) When a dog's life is a burden to him it is unfair to keep him alive and he should be put to sleep. It must be realised, however, that putting a dog to sleep is a very skilled task. It is made much easier if an owner will allow his veterinary surgeon to administer an anaesthetic and not allow the animal to come round, and shooting is also straightforward and painless if skilfully carried out. There are no magical ways of destroying human or animal life and an owner must not expect his veterinary surgeon to be able to bring about death merely by holding a pad to the dog's face. It is far better that the task be carried out at a veterinary surgeon's own premises where there is skilled assistance.

CATS

Many of the general remarks in the preceding section apply equally to cats and will not be repeated unnecessarily in the following paragraphs.

BREEDS AND VARIETIES OF CAT

The following breeds and varieties are recognised for registration purposes by the Governing Council of the Cat Fancy—

Long haired Cats

Black	Tortoiseshell
White (Blue-eyed)	Tortoiseshell and White
White (Orange-eyed)	Blue Cream
Blue	Brown Tabby
Ped Tabby	Chinchilla
Red Self	Smoke
Cream	Silver Tabby

Short haired Cats

Black	Spotted
White	Russian Blue
British Blue	Manx
Cream	Abyssinian
Tortoiseshell	Siamese (Seal pointed)
Tortoiseshell and White	Siamese (Blue pointed)
Silver Tabby	Siamese (Chocolate pointed)
Brown Tabby	Burmese
Red Tabby	
Mackerel striped Tabby	

Pedigree breeding and showing are practised with a very small fraction of the total cat population of Great Britain and the majority of these remarks will be concerned with the ordinary household cat. Nevertheless in recent years there appears to have been a considerable increase in pedigree cat breeding. Registration—which is essential for showing and pedigree purposes—is controlled by the Governing Council of the Cat Fancy. Many of the breeds listed above have their own societies which are affiliated to the Governing Council. The addresses and particulars of these and other cat societies and clubs may be had on application to the secretary of the Governing Council. The two most popular varieties of cat are the Blue Persian and the Siamese and an exclusive show is held for each of them. In addition to these shows there are five big Championship Shows open to every variety of long and short-haired cat while there are classes for cats and kittens at some of the Agricultural Shows.

CHOICE OF CAT

Although there are as noted above, many varieties of cat most people are content to accept an ordinary kitten and for them the chief points to consider will be (a) whether to have a long haired or a short haired animal, (b) whether to have a male or female, (c) whether or not to have the kitten doctored (i.e. castrated or spayed). As a general rule, short haired cats are probably more suitable for the average household since their fur does not become shed so noticeably and they probably suffer less from fur-balling. Nevertheless many long haired cats are so attractive that they will obviously be preferred and there is no reason why they should not be chosen. Sex is a rather more important question although, as may be seen in the section on management it is possible to have both males and females doctored. Male cats which are kept as entire are often a nuisance in that they make abominable smells in the house and spend much of their time in fighting. These characteristics are by no means invariable but they are so common as to justify the castration of the majority of males. Siamese males in particular may be a liability. Females are generally credited with a greater attachment to the home (although they wander when in season) and with being better mousers. The principal objection to females is that they seem to be bearing kittens almost continuously. In normal circumstances it is of course quite impossible to prevent cats from mating by keeping the female in confinement.

during her season a practice which is frequently adopted in the case of the dog. For one thing, most people are never aware when their female cats are in season.

Whatever animal is chosen it is essential to pick a healthy and preferably a fairly young—but not too young—kitten. It is best not to accept a kitten under about eight weeks of age.

For those who wish for something a little out of the ordinary, Siamese cats are male, excellent and highly intelligent pets. Siamese kittens are born white but gradually develop their even pale fawn colour with cream on belly and chest and with seal brown mask, ears, legs, feet and tail. The coat is very short and the eyes are blue. There has long been a popular belief that Siamese cats are delicate creatures, but the present writer has seen healthy specimens kept under ordinary household conditions living to a mature age. It is not wise to keep a male Siamese as a household pet. The male is a fierce fighter and is generally a worse offender in the house than the males of other breeds and should therefore be castrated if it is to be kept as a pet.

Many people find Manx cats attractive. Instead of the normal large number of tail bones they have but three and hence appear almost tailless. One should beware against fraudulent amputation of the tail of ordinary cats which are then described as Manx.

MANAGEMENT OF THE CAT

The cat is an independent creature so much so that one may say that to a large extent it manages its own affairs. This however is not true of all cats and every reasonable attempt should be made to provide the cat with a comfortable and friendly home. Cats are highly intelligent and if sufficient patience is exercised they will respond to a very great degree to human attention. Kittens should not be neglected but should be talked to and played with just as are puppies. Many cats, especially young cats, make excellent playmates for children.

In order to prevent to a large extent their nocturnal wanderings many cats of both sexes are castrated or spayed (the popular lay expression for this is 'doctored'). In the male cat the testicles are removed by an operation which is almost always safe and simple if carried out skillfully. From three to four months is a good age at which to have this done. Female cats may also be 'doctored'. As the female glands or ovaries lie within the body cavity this operation is a major one but it is nevertheless quite a straightforward though a more expensive procedure if conducted at the right age (about five months). Very many thousands of female cats have been so operated upon and the subsequent health of these cats has been excellent. Indeed it has been said that a spayed female makes one of the best of all household cats.

Cats may choose to sleep in a variety of places and will often lie on beds, chairs, mats, and other warm places. It is a sound policy to provide them with a box or basket and to encourage them to use newspaper as a bedding. Most cats will take well to newspaper. The bed should be placed in a warm site—it is of little use putting it in a cold corner of a room and expecting the cat to lie in it.

Owing to the fact that even in play a cat's claws may inflict serious injury dogs and cats do not always make the best of house companions. Nevertheless the traditional enmity of cat and dog is often overcome, and if the two are brought up together they often make firm friends sharing the same basket or hearth rug and feeding together without serious consequences.

A cat normally attends to its own toilet and everyone must be aware that a cat devotes long periods each day to cleaning and washing itself. Except in special cases therefore bathing is quite unnecessary while in short-haired cats especially grooming, too, is superfluous (this does not apply to show-cats). For some reason (and sometimes, apparently because an owner attempts to assist in the daily grooming) an occasional cat may cease to wash or care for itself. Such an animal is a defected sight and should be taken to a veterinary surgeon to have its matted fur cut or combed and

its dirt removed. Such animals (unless they completely reacquire their self respect) must be groomed regularly if they are to be kept at all.

All household cats are accustomed to take their own exercise and it is advisable (except in any special circumstances) to allow them free access to and from the outer world. Do not shut your cat in the house for a long period and then blame it for making a mess. Cats are clean creatures; they normally dig small holes in which to defecate or urinate and subsequently cover the deposit with earth. If therefore they are for some reason debarred temporarily or permanently from access to a garden they should be provided with a box or tray containing soil or cinders. Indeed in many types of houses it is a good plan to encourage kittens to use such a device. (Note the corresponding remarks about puppies.)

It is generally stated that cats never forget a blow and for that reason it is recommended that cats are not chastised. It may be said that if a cat (or dog) be brought up conscientiously and well, it should never or very rarely require such punishment. An animal which has been brought up properly seems to develop a fair sense of what is right and what is wrong.

For pedigree cats or those kept in confinement for other reasons, see the relevant remarks in the section on breeding.

FEEDING THE CAT

Although most cats are capable of supplementing their diet by catching small rodents or birds it is unwise to rely on this as a regular source of food. The idea that hungry cats make the best mousers is by no means always correct. Indeed animals that are in poor condition are less likely to be successful hunters. Moreover while the riddance of pests is an excellent matter from the human point of view—and one of the reasons why the keeping of cats is economically justified—the cruel fashion in which most cats tackle their prey is repulsive to most of us.

It is therefore necessary and desirable to provide regular daily feeding. Kittens should receive several meals a day but by the time they are six months old the number of daily feeds should be reduced to one or at most two. Most cats (many Siamese are exceptions) are extremely fond of milk, especially if it is creamy and the cat's love of fish is well known. Many meats, especially rabbit meat, are relished and diet high in animal protein is indeed the aim, always provided that it contains sufficient dietary energy. It is significant that cat's milk has a higher content of fat and sugar than cow's milk, i.e. it is a richer source of energy. Some of the proprietary bitch milk substitutes are nearer to cat's milk in composition than is cow's milk.

Many hundreds of cats have been reared and bred successfully in experimental laboratories on a diet consisting in the main of one part of fish or meat and two parts of *cooked potatoes*. This is relatively inexpensive and may be supplemented by milk and by some of the proprietary cat foods.

Cats are also extremely fond of liver. Some of the proprietary cat foods—the better ones of which are excellent—and vitamin tablets contain liver which is a rich source of the vitamin B complex.

Within reason a healthy kitten should be fed to appetite always provided good quality foods are available. The amount should be restricted when they are adult however except for pregnant and lactating cats which are sometimes referred to as 'queens' as opposed to the male 'toms'. An average daily allowance of solid food for a healthy non-pregnant adult cat should be of the order of $\frac{1}{2}$ oz per 1 lb body weight.

Cats are fastidious eaters; they usually sniff and examine carefully any strange or doubtful food. At the same time they are often greedy especially with relished food to which they are accustomed but fortunately they can, like dogs, vomit very readily. Here incidentally is one very good tip—an excellent emetic for both cat and dog is a small crystal of washing soda given as a pill. People are usually amazed at the way this simple device results in a dog's or a cat's bringing up undigestible food.

It is important not to overfeed cats, and it is

almost equally important to prepare all food in a clean manner and to make it as attractive as possible. Cats will greatly appreciate this care. While milk is an excellent food for kittens (see under breeding) and is relished by most adult cats it must be supplemented by solid food.

Clean fresh water should be provided at all times even if the cat appears to drink it but little.

BREEDING OF CATS

Pedigree animals are normally confined, and their breeding is strictly controlled. Ordinary household cats are at the opposite extreme and there is little that can be done to prevent their mating. The length and scope of this article does not permit of a discussion of controlled mating.

Scientifically there is as yet a good deal to learn about the reproductive behaviour of the cat. As an American physiologist has succinctly put it in a description of the reproductive cycle of the female cat, no two authors agree. In Northern Europe there are two main heat periods a year in spring and early autumn but some animals may appear in heat at any time from January to July and those who keep female cats in confinement describe their charges as calling quite frequently if not mated. A cat which is in season or on heat is often observed to be behaving in a quite characteristic fashion, rolling about on the floor and making peculiar sounds. The periods of heat which commence usually at about eight months of age may last for several days and during this time the female will make every attempt to find a mate.

Gestation lasts about nine weeks as in the case of the bitch but here again there is a considerable variation. As most owners are quite unaware of the time at which their cats were mated it is difficult to talk of going overtime but if there is any evidence of trouble during pregnancy or at birth veterinary advice should be obtained. As soon as a cat is obviously pregnant her food allowance should be increased and she should be allowed plenty of milk. It is highly important to increase her food and milk ration still further after the kittens are born, as lactation is a great drain on the mother.

Cats sometimes choose strange, out-of-the-way places in which to litter and many healthy litters are born and reared out of doors. Cats are a source of danger and will often destroy very young kittens during the mother's absence. For this and other reasons it is better in town and suburban areas to have the litter comfortably housed indoors. A wooden box containing newspaper is ideal provided it is kept in a fairly warm place and out of the way of draughts. An average litter consists of three to six kittens, which are born blind but which normally open their eyes after eight or nine days. There is no need to be alarmed if the eyes remain closed for a few days longer. Kittens which are born dead should be removed and buried or burnt. If the whole litter is born dead the mother's food supply should be cut down considerably and little milk given for a few days. If the mammary glands become inflamed they may be bathed in a cold solution of alum. The glands normally return to their former size within a short space of time if they are not milked, but if there is persistent trouble veterinary advice should be sought.

While many pedigree owners wean kittens at four to five weeks of age, it is strongly advised that the household cat be allowed to continue to feed her family for a longer period and eight weeks is not too long if the mother is still in good bodily condition. She must, however, be well fed and be allowed plenty of milk. As in the case of puppies it is an excellent idea to provide the kittens with a little solid food as from a few weeks of age. It is very wrong to remove a kitten from its mother too early and such an animal is often weakly develops an intestinal infection, and dies as a miserable bedraggled creature. Moreover during the period following weaning the mother educates her offspring in the art of living, particularly sitting and mousing.

As many litters are unwanted, some people get rid of all the kittens as soon as possible after birth. Drowning is frequently practised but it is not

recommended as a merciful death. Indeed a hard blow on the back of the head is more humane if given accurately. It is much better to take the kittens to a veterinary surgeon or clinic.

DISEASES AND INJURIES OF THE CAT

The principal infectious diseases of cats are still in need of much scientific study. It is now clear however, that there are at least two major cat plagues. Both have been given many names and there is much confusion between them.

Feline Enteritis or Panleucopenia.—This is a highly infectious disease due to a filterable virus. The symptoms include loss of appetite sometimes accompanied by a rise in body temperature followed by listlessness usually vomiting some times diarrhoea and a marked tendency to show tenderness or pain on being handled. This tenderness or pain is due to a developing peritonitis. The poor animal may become seriously ill, with loss of water from the tissues or dehydration, prostrate and dead within 48 hours or less from the time of the first symptoms. The incubation period of the disease is believed to be from 4 to 8 days or sometimes longer. There is a fall in the white-cell count of the blood hence the term panleucopenia. Some cats recover the recovery rate in different outbreaks that have been studied ranging from 30 to 80 per cent and recovered animals are probably immune to further attacks. Cats that are able to take a little food during the early stages of recovery have the best chance of recovery but require careful nursing. There may be complications during the convalescent stage due to secondary bacterial infections or to vitamin deficiency and a light nourishing diet combined with vitamin preparations is recommended. Fleas may transmit the disease to other cats as may contact with infected materials. It has been shown that bedding and dirt trays from sick cats were infectious for other cats for up to 16 days. The disease is not transmissible to dogs or to human beings. There is nowadays a protective vaccine and it is a wise precaution to have your pet vaccinated.

Feline Pneumonitis.—This disease is sometimes called cat distemper—as indeed is feline enteritis—but it has no connection with dog distemper and is not transmissible to dogs or to human beings. Both mild and severe forms occur and the incubation period varies from 5 to 8 days. The mild form may seem like a cold, and there is a weeping from the eyes and a varying degree of conjunctivitis. There is a thin, clear discharge from the nose with a characteristic sneezing. Provided that the animals can be made to continue eating and are kept in warm and dry but ventilated conditions recovery may be rapid and not entail serious loss of condition. The eyes should be treated with a suitable preparation such as silver vitellin. There may be secondary bacterial infection in cases that are neglected.

The severe form of the disease has similar although more severe commencing symptoms, but the nasal discharge becomes purulent and there is often profuse salivation, with much spreading of the long ropes of saliva. The cat is listless, dislikes strong light, and seems to resent being disturbed. It loses its appetite and rapidly becomes thinner over a period of from 2 to 5 days or so. Breathing becomes laboured, and a bronchopneumonia develops. There may be a high death rate in young kittens, and pregnant females may abort. Recovery tends to be slow and is often complicated by bacterial infection. Some of the modern antibiotics appear to be highly effective in the treatment of many cases of this disease but they must of course be given under veterinary supervision.

Tuberculosis.—The cat like the dog can contract tuberculosis but so far as is known only the bovine form has been known to infect it. The infection usually comes, of course, from milk and the elimination of bovine tuberculosis from this country will stop the incidence of the disease.

in cats. The disease commences in the abdomen but may spread to the lungs. There is general wasting.

Skin Diseases—As in the case of the dog, skin disease in the cat is usually of parasitic origin and fleas and mange mites are again the chief source of trouble in Great Britain. Cats do so much of their own toilet that the average household cat has probably a cleaner skin than its canine counterpart. When skin disease does develop it is strongly advised that the animal be taken to a veterinary surgeon for appropriate treatment. As a rule cats greatly resent the interference which must accompany any attempt to bathe or dress an affected place and for this reason it is usually unwise for an owner to attempt to do other than make an inspection. Very small patches of skin eruption may clear satisfactorily if the surrounding hair is clipped away with curved scissors but generally speaking skin disease calls for professional attention. The cat flea has a similar life cycle to the dog flea (see Z8).

Diseases of the Ear—The outer ear of the cat is frequently affected and in a great many cases a form of mange mite is responsible. The animal provides evidence of the trouble by scratching and shaking its ear and generally shows signs of discomfort. It will not always be possible for an owner to make a thorough examination as in many cases the cat objects but if it is possible to look inside the ear it will be seen that there is a dirty and usually brownish mess of tissue, sometimes mixed with dried blood or pus. Not all cases are as bad as this of course but if a cat persistently worries its ear it should be taken to a veterinary surgeon. There are satisfactory dressings for this condition and owners will be able to dress their cats if the latter are docile. Otherwise it is necessary to have the ears dressed by a veterinary surgeon or by one of his staff.

A cat's ear is frequently the site of a blood blister or hematoma. This is usually the sequel to a blow such as a slamming door and shows itself as a large tense swelling which when opened by a surgeon proves to be an accumulation of serum usually tinged with blood. Some cases become infected at the time of injury some after with the patient's rubbing. With the greatest surgical skill in the world one must expect a slight deformity and the cat develops a puckered ear much the same as the human boxer.

Disease of the Bladder—The bladder is a common seat of disease in cats and is frequently affected through the blocking of the natural water passage by small sand like calculi. Naturally male cats are more often affected at the terminal end of the urinary tracts is wider and more dilatable in females. The urine is unable to escape and the bladder becomes filled with a mixture of urine and the sandy calculi matter. The condition may be diagnosed quite readily as the cat usually collapses or partially collapses and one may easily feel the distended bladder through the walls of the abdomen (belly). It is necessary to send for professional help immediately and while no relief can be guaranteed it is often possible to relieve the condition by judicious manipulation. Owners should not attempt to do this themselves (unless help cannot be obtained) as they may easily burst the bladder. As the animal is usually in a state of collapse when the condition is discovered it makes a bad risk for actual operation and relief by skilled pressure is usually to be recommended.

Ringworm—There are two common kinds of ringworm in the cat (a third which may also infect the dog is more rare). It is the trichophyton which is usually found on cattle. The first kind is acquired from rats and mice and is most commonly to be found at the bases of the claws from where it may spread to the ears and face. The individual lesions are circular and yellow in colour and consist largely of a scabby material. This kind of ringworm is known as favus.

The second type of ringworm (microsporon) is more important because it is more readily transmissible to human beings. Whereas this form

usually sets up circular scaly lesions in the dog it often infects cats without there being much naked eye evidence of its presence. Indeed in the cat the condition is often unsuspected until the owner himself becomes infected and consults his doctor.

Ringworm should be treated or dealt with by a veterinary surgeon who will also confirm or refute by special methods the presence of microsporon in cats.

Intestinal Parasites—Worms—The cat also is subject to both roundworms and tapeworms. The roundworm which parasitises cats in this country is similar to that of the dog (although a different species) and is also much more harmful to the young than to the adult animal. In kittens the symptoms are a general unthriftiness, staring coat and in some cases diarrhoea and a pot bellied appearance.

The commonest cat tapeworm in this country is one which passes its intermediate stage in the rat or mouse or sometimes in other rodents. The tapeworm which as mentioned under the section on dogs is dangerous to man is sometimes found in the cat also.

Accidents and Injuries—Despite their sagacity and alertness in many ways cats seem curiously unable in many instances to acquire road sense. They are dazzled by a car's head lights while if a motorist sounds his horn they tend to stop still in their tracks.

Injuries from traps e.g. gin traps are very common and it is probable that many thousands of cats annually are maimed in this fashion. Cats suffer injury from shooting from stoning and from blows with sticks. Since they are predatory animals they have often to pay the penalty inflicted on them by wrathful people. Needless to say cats which survive to return home usually require expert treatment.

Poisoning may be included under this heading. Although there are doubtless many deliberate attempts to poison marauding cats alleged poisoning is often no more than a case of feline enteritis and owners should not claim glibly that their cats have been poisoned until they have expert evidence to back their judgment.

Fur baling as it has been termed may be mentioned here. Cats especially the long haired varieties must often ingest hair during their toilet and occasionally serious trouble (a stoppage of the bowels) is brought about by a mass of such hair which has collected in a part of the bowel. There is constipation, loss of condition and often evidence of considerable pain. Such cats should be taken to a veterinary surgeon.

Bites and scratches are even more common in the cat than they are in the dog and subsequent sepsis is equally likely.

FERRETS

Description—The ferret is probably a domesticated form of the pole cat (*Mustela putorius*) and is known sometimes by that name and sometimes as *Mustela furo*. Most tame ferrets have pink eyes and yellowish white fur but there are darker forms believed to have resulted from crossing in previous generations with wild pole cats. Indeed these darker forms are popularly termed pole cat ferrets. They are of two main kinds, the first having creamy under fur and black guard hairs and the second being a chocolate brown colour with brown upper parts and black under parts and a few scattered light hairs on the face.

Ferrets are long creatures in relation to their body weight and when fully grown may have a body 14 in. long or more and a tail of 5 in. Some strains grow appreciably larger. The main use of the ferret is of course, in rabbiting for which purpose they have been employed for many centuries. Although they can become fierce if not accustomed to regular handling or kind treatment and are capable of inflicting a nasty bite they may nevertheless be made into docile and highly intelligent pets. It is most important to win their confidence from the beginning and to accustom them to regular handling from the time they are young kittens.

Accommodation—Ferrets must have dry clean accommodation in a room free from draughts but well ventilated. Wood is warmer than metal, but more difficult to clean and is best lined with hard asbestos sheeting which is resistant to water. The most suitable accommodation comprises a sleeping compartment of similar proportions to a small kennel leading by a small doorway or pop hole to a wire netting exercising run which should be as large as possible compatible with cleanliness. It is a good idea to have a means of closing the doorway so that the ferret or ferrets may be confined within the sleeping compartment if necessary. Wood wool makes an excellent bedding but if difficult to obtain newspaper may be provided for the ferret to lie on. The floor of the run may have a false bottom or may be sprinkled with sawdust. It is imperative to keep the whole of the accommodation clean and dry not only to avoid smell but also to prevent the ferrets from developing a very serious necrotic infection of the feet known as foot rot.

Feeding—Many ferrets are unfortunately not fed adequately. It must be appreciated that basically they are carnivorous animals and that their food requirements are more similar to those of the dog and cat than those of rodents. In deed many of the general remarks made about the principles of feeding dogs and cats apply to ferrets also.

Most ferrets like bread and milk and while this is an excellent article of diet it is in itself inadequate. Up to about 4 oz of raw meat (minced for younger animals) daily is an excellent basis and this may be replaced by fish. Liver especially raw liver is an excellent source of many factors and there is good reason to provide some at least weekly if it can be obtained. Feeding this it is advisable to add 1-2 per cent of whole dry liver to the diet. Once ferrets are grown one feeding daily—at a fixed time—is sufficient. The female (jill) should have ample supplies of milk just prior to the birth of her young and while she is suckling them.

Breeding—In the northern hemisphere the female ferret usually comes into oestrus (season) in early March of the year following that in which it is born. If the jill does not conceive during this oestrus she will have a further oestral period in July or August. The desire of the jill to mate is very strong and if not allowed to do so some animals sometimes have been found to waste and pine. The act of mating is prefaced by very vigorous behaviour on the part of the male (hob) and anyone not appreciating the performance might think that he was out to kill his mate! The mating act itself is usually prolonged and may take up to three hours. If left together the hob and jill will probably mate from two to four times during the course of a couple of days. As in the cat and rabbit ovulation or the shedding of the egg from the ovary takes place as a result of mating and not spontaneously. The period of gestation is forty two days and the numbers of young born usually varies from five to thirteen the average litter being six to eight. Pseudo pregnancy occurs if the jill is not mated and may become outwardly obvious as in the case of certain bitches.

Males also have a seasonal rhythm their capacity to fertilise being greatest from early March to August. Young hobs seem to be active about a month earlier than older ones. The length of daylight or rather the incrementation in light from day to day has an important bearing on breeding capacity in both sexes and by the use of artificial light it has proved possible to induce either oestrus or male activity at different times of the year.

The young are hairless and blind and weigh on the average under 1 oz at birth. Their eyes open at about four weeks and they can then commence to eat small pieces of solid food to supplement their mother's milk. They may be weaned at from six to eight weeks.

Diseases—The most serious disease of ferrets is canine distemper and the variant known as

hard pad (see under dog) is equally capable of infecting ferrets. Such infections can wipe out entire stocks and every care should be taken to prevent their spread from dogs to ferrets—and vice versa. A veterinary surgeon should be consulted immediately when a ferret becomes ill or out of sorts. Ferrets are also susceptible to some strains of human influenza and should not be tended by persons with colds or with any indications of flu. The feeding of infected milk may give rise to tuberculosis (now unlikely in Britain). Foot rot has already been mentioned and must on no account be neglected. Mange or scabies of the back and tail region should be dealt with promptly employing modern preparations. Abscesses of the neck region are often encountered and should receive professional treatment if they do not clear up rapidly for they may spread with dire consequences.

RATS

Description—Tame rats are domesticated varieties of the wild Norway or brown rat (*Rattus norvegicus*). Such rats are usually albino or black and white although other colours have been bred. The hooded varieties are those in which the head and foreparts are mainly black or chocolate and the remainder of the body apart from small patches the same colour as the hood is white. Tame rats differ materially from wild ones in disposition and properly managed are extremely tractable. Healthy specimens accustom to handling bite only when frightened e.g. when a sudden movement is made in front of them. Males appear to live longer than females but three years is a good age.

Black rats are the species (*Rattus rattus*) sometimes known as the ship or Alexandrine rat have been bred in captivity but tame strains are not generally available.

Housing—Tame rats require a warm even temperature—65-70° F all the year round—and draughts or lowered temperature may precipitate lung disease or other disorders. It is best to have a complete spare set of boxes or cages and to change to fresh quarters weekly except when the females have unweaned young with them. Empty cages should be cleaned and disinfected thoroughly before being used again. Provided the temperature conditions are suitable—and this is essential—metal cages of the types employed in scientific laboratories are best with wire mesh false bottoms and trays containing sawdust to catch the droppings. Accommodation should be

ample and even for a pair of pet rats the cage should measure about 30 in. x 18 in. x 18 in. If wooden boxes are employed it may be desirable to line them with hard asbestos sheeting or galvanised metal to prevent damage from gnawing.

Small dark shelters and exercising devices e.g. wheels or ladders, are appreciated by the rats, but must be kept clean. Wood wool makes the best bedding.

Feeding—Rats may take a wide variety of foods including many of our own and there are

several successful ways of feeding them including the provision of specially formulated rat cubes of the same type as that described below for mice. A good daily diet is wholemeal bread mixed cereals (e.g. oats wheat hempseed) with about

WATER BULB SUITABLE FOR USE WITH PET RODENTS

5 per cent dried brewers yeast and milk either fed separately or mixed with the rest of the food. Twice weekly each rat should be given up to $\frac{1}{2}$ oz or more of meat liver fish or other animal protein. A little fresh greenfood (even grass) is appreciated and in winter especially some supplement containing vitamins A and D is desirable. Expectant and nursing mothers should have as much milk as they require. Never overfeed or allow uneaten food residues to remain in the cage. Fresh water (preferably in bulbs or bottles) should be available at all times. For cleaner than open dishes are the special but simple type of water bulbs suspended on or in front of the cage or box so that the rat can drink from the rounded end of the spout. A simple substitute is a medicine flat bottle—or even a $\frac{1}{2}$ or $\frac{3}{4}$ pint milk-type bottle. This should be fitted with a cork—or better a rubber bung—pierced for a piece of bent glass tubing. Provided that the free end of the glass tubing is not sharp and is chosen so that the aperture is considerably smaller than that of the tube itself the water will not run out unless sucked out by the rat. The spout should of course be within easy access of the rat which will soon learn to drink from it.

Breeding.—Rats can breed at quite a young age (usually being capable of mating when fifty to sixty days old) but it is better to separate the sexes within a fortnight or so of weaning (weaning being usually at twenty one days of age) and to mate at about 100 to 120 days of age onwards. The female rat has an oestrous cycle lasting just over four days. One male (buck) may be mated to one female (doe)—this is probably best in the case of pet rats—or with two or three females if preferred but it is unwise to keep more than one adult male in the presence of females. The gestation period is twenty one to twenty two days or occasionally a few days longer. The number born varies considerably but often it is best to try to rear only six to eight young. The young have their ears open at $2\frac{1}{2}$ to $3\frac{1}{2}$ days cut their incisor teeth at eight to ten days can find their way to their mother at about the same time open their eyes at fourteen to seventeen days and may leave the nest at twenty one days. In the case of pet rats it is probably best to leave the young with the mother for up to a week or so longer. Breeding can occur all the year round but takes place less readily in winter.

Handling.—Rats should not be tailed or the skin may slough off. Regular handling after weaning is excellent and promotes docility. The weight of the body should be supported.

Diseases.—On the whole rats are much less liable to disease than mice provided temperature conditions are suitable. The commonest infection is *broncho-pneumonia* often precipitated through

draughts or cold. Mange (especially of the ear) and infestation with lice may occur and should be dealt with promptly by means of modern insecticides. Avoid contact with wild rodents or the use of food or bedding that may have been contaminated by wild rats and mice.

MICE

Description.—Tame mice are descended from the common house mouse (*Mus musculus*) and it is believed that mice have been domesticated for over 3 000 years. Apart from albino or white mice there are many varieties that have been bred by the extensive mouse fancy and there is a wide range of coat colour and also different types of coat e.g. long haired short haired and rex. Waltzing mice have an abnormality of that part of the inner ear concerned with balance. Mice may live up to thirty months and in exceptional cases attain the age of three years or more.

Housing.—Although strains vary most tame mice require a warm even temperature and the same general remarks concerning temperature range bedding and wooden or metal cages apply as in the case of rats. If a solid floor is used this should be covered with clean sawdust. It is a good plan to change to a clean cage regularly except when the female (doe) is nursing her young. If the cage is large (as in the case of pet mice it should be with a floor space of say 24 in. \times 12 in. \times 12 in for a group of mice) inner nest boxes should be provided—one for each doe if breeding is taking place although two does will often share the same nest box. (In changing to fresh cages the nest box with mother and young inside may of course be moved over.) A two storey cage with a ladder or staircase to the upper part is an attractive variation although difficult to keep clean. Mice should be kept well out of reach of wild rodents from which they may all too readily contract disease.

Feeding.—Mice have not quite such a wide dietary range as rats but there are several different ways of feeding them, including the provision of special mouse cubes. These mouse cubes are of varying composition. One of the most successful devised by workers in the Medical Research Council's laboratories is known as Diet 41 and is made up of the following parts by weight: wholemeal flour 45, Sussex ground oats 40, fish meal 8, dried yeast 1, dried skimmed milk, 3, cod liver oil 1 and common salt 1. Diet 41 has also been employed for rats and monkeys although for the latter particularly it requires supplementing. It is perhaps worth emphasising that cod liver oil must not be fed in excess ($\frac{1}{2}$ % of the diet is quite sufficient and should not be exceeded) or it may prevent breeding and possibly have other harmful effects. Cubed diets are best fed from a wire basket through which the mice enjoy gnawing and eventually pulling out the pieces. Wholemeal bread is excellent if not allowed to become stale but it should not form the sole article of diet and it is a good idea to feed it alternately with a grain mixture (made up of rolled oats, wheat and other cereal grains or mixed bird seed). Up to about 5 per cent dried brewers yeast is excellent and so is fresh or dried milk, especially for mothers that are carrying or nursing young. Cheese is relished but may smell if not fed carefully. Mice sometimes like an occasional pinch of marmalade and it is a good idea to provide lettuce or other greenfood every week or so. There should be a constant supply of fresh water preferably from bulbs or bottles as described for rats.

Breeding.—Young mice may be weaned at twenty one days although it is usually preferable to leave them with their mother for a further week. The age at which mice are capable of mating varies considerably from one strain or individual to another and while the average is six to eight weeks, it may be much younger. It is therefore desirable to separate the males from the females at or shortly after weaning.

Mice may be mated up at two to three months of age and the best arrangements are one male (buck) to one or two females. A pair of mice or a bigamous trio makes a successful combination. The oestrus cycle is similar to that of the rat but its length appears to vary with coat colour being longest in the brown mice and shortest in blacks and albinos. The gestation period is usually from eighteen to twenty days but may be prolonged if the female was still suckling her previous litter when she conceived. There may be up to twelve or more young in a litter but the average litter size is from five to seven. The second litter is usually the largest and subsequent litters tend to decrease in number so that the sixth is usually smaller than the first. Breeding may take place all the year round, although as with rats fertility is higher during the summer months.

Handling—Any rapid or rough movement may frighten mice and cause them to bite through fear. Mice should be lifted by the tail—not too near the tip—and may be held in the palm of the hand where they may be suitably restrained by keeping the tail between two fingers.

Diseases—Mice are unfortunately prone to many diseases although the risks will be much lower if they are kept in suitable surroundings. Great care is taken to avoid infection, scrupulous cleanliness is observed and the standard of feeding is good. One common source of infection is the presence of the excreta of wild rodents on bedding or foodstuffs. A common disease is that sometimes called *mouse typhoid* caused by organisms of the *Salmonella* group. Although some mice recover they may remain carriers of infection and once this disease is diagnosed it is best to destroy the affected mice and those in contact with them and not to employ any of the cages or utensils or fresh mice without adequate sterilisation. There are other septicæmic diseases of mice and also virus diseases including certain types of *pneumonia* and a condition known as *infectious ectromelia*. The accurate diagnosis of these calls for expert opinion and often for special bacteriological or other examinations. The mouse owner should however be able to recognise signs of ill health or departure from normal, one of the commonest being loss of appetite. In young mice the coat should be smooth and glossy. As mice get older there may be loss of pigmentation (in coloured mice) or even loss of fur. A sick mouse usually sits hunched up and has a ruffled coat while the eyes may be partially closed or have some discharge. A healthy mouse will usually catch on to suitable objects when held by its tail and is capable of pulling quite hard, whereas the pull of a sick mouse is much weaker. If one or more mice die it is best to destroy at once any cage mates that appear seedy. As in the case of rats external parasites should be dealt with promptly with the aid of modern insecticidal preparations.

GOLDEN HAMSTERS

Description—There are many species of hamsters in the world and more than one kind can now be bred in captivity. The one referred to however is the Golden Hamster (*Mesocricetus auratus*) a delightful little creature of which a full grown female (females are larger than males) rarely exceeds 7 in in length. This history of the domestication of the golden hamster is quite remarkable for prior to 1880 only museum specimens were known. In that year a mother and her twelve young were dug up in a field near Aleppo and were taken to the Hebrew University, Jerusalem, and from that one family have been bred the hundreds of thousands of golden hamsters now employed as pets or as laboratory animals in many parts of the world. The species has taken well to captivity and, although capable of inflicting a nasty little bite if frightened or handled roughly becomes docile and friendly when properly cared for. Characteristic features are the soft smooth fur, the large black eyes, the cheek

pouches in which food is stored and which may become enormously distended after a meal, the short stumpy tail and the extremely loose skin inside which the hamster can turn round to a considerable degree.

Housing—The same remarks about accommodation, environmental temperature, freedom from draughts, fittings and other general considerations (including cleanliness) apply as in the case of rats and mice. For breeding purposes a dark inner chamber or nest box is desirable. Several hamsters may be kept together but the introduction of a stranger (or even the re-introduction of a former cage mate that has been removed for some time) may lead to fighting.

Feeding—Satisfactory diets include the following: (1) rat cubes (e.g. Diet 41), (2) carrots, greenfood and milk, (3) cereal grains and/or wholemeal bread, (4) carrots, greenfood, and milk, (5) steamed Rangoon beans, wheat, maize meal, bread, a little Marmite and milk. Care must be taken not to allow storage of excess food which will deteriorate and cause a smell. Grass is a suitable source of greenfood during its growing season. Apples and other fruits are often refreshed. Water preferably in bulbs or bottles as described for rats should always be available.

Breeding—Golden Hamsters attain puberty at from ten to fifteen weeks of age or even younger, males being usually earlier. Generally speaking it is best to defer breeding until after fifteen weeks of age. There is an oestrus cycle of about four days and the gestation period is very short, averaging sixteen days although sometimes up to nineteen days. Mating not followed by conception results in phantom or pseudopregnancy. Litter size varies from one to fifteen, but the average is six to seven. Not many females have more than four litters and although both sexes may live up to two years breeding by the female is rare after nine months. The young are naked and blind at birth. Hair first appears at five days and covers the whole body at eight days. The eyes open at about eleven days and soon after this the young begin to take food for themselves and may be weaned at three to four weeks. Care must be taken that the female does not injure the male and for safety's sake it is probably better to keep only one female and one male together and to remove the male before the young are born.

Handling—Gentleness is essential and sudden movements should be avoided. The tail is much too short to use and the easiest way is to lift them by the loose skin over the back and shoulders. As already noted they can twist easily within their skins unless a substantial amount is taken in the hand. After picking up they may be allowed to sit on the palm of the hand.

Diseases—Several diseases of hamsters are now known, and, like most rodents, they are susceptible to *Salmonellosis* (see notes under mouse typhoid and paratyphoid in guinea-pigs). One of the most prevalent conditions is *ear mange* in severe cases of which the condition spreads from the ears to other parts of the body. Modern anti-mange preparations are highly effective.

CAVIES (GUINEA-PIGS)

Description—Cavies or guinea pigs (*Cavia porcellus*) are rodents, and are descended from one or more of the several kinds of wild cavy found in South America. They are believed to have been domesticated by the Incas long before Europeans discovered that part of the world. They make excellent pets but are easily frightened and should be treated gently and quietly. They usually behave quietly although there may be fighting between adult males (boars) while the arrival of food—or the entry of a person into a room, which fact is obviously connected with feeding time—usually sets up a chorus of chirrup-

ing squeals. There is to day a considerable cavy fancy. In Great Britain and other countries and many varieties are recognised including rough coated and smooth coated types. Among recognised colours are the agouti (banded hairs) brindlé (mammón tortoiseshell (micoloured) and Humáyan (white with attractive black points). The long haired Peruvian and rosette haired Abyssinian breeds are popular. Guinea pigs may live up to two to three years. There is a small tail (composed of from five to seven caudal vertebrae) but usually this is so short that it does not project outside the body. There are four toes on each of the fore feet and three on each hind foot. An adult guinea pig may measure up to 10 in. or more in length and some times its weight is well over 2 lb.

Housing—Guinea pigs may be kept outside or inside. If outside conditions are favoured great care must be taken to protect them from dogs, cats and rats. The last named may be a danger also in conveying disease. The run should be in a sheltered position away from wind and direct summer sunlight. Tent shaped waterproof shelters with wooden floors covered by cleaning trays have been found satisfactory. Another method is to keep them in hutches of the same type employed for rabbits and when conditions are suitable to let them out into a temporary run on the lawn surrounded by 1 in mesh wire netting that is at least 12 in high. (N.B. This will keep dogs or cats out.) Guinea pigs will crop the grass and help to keep the lawn smooth. Great care should be taken not to allow the ground or floor to become so contaminated by guinea pig excreta that it conveys disease from one animal to another.

If indoor methods are selected an even preferably warm temperature is desirable and there should be freedom from draught. Guinea pigs have been found to thrive best at about 65° F with a humidity range of 45–55 per cent. Provided warm conditions are available metal cages are easier to keep clean than wooden ones while a false bottom of wire mesh above the clean tray is helpful. Wood wool is again the best bedding. Cages must not be too small and a pair of pet guinea pigs should have about 14 sq. ft. of floor space. It is a sound principle as with rats and mice to change frequently to a clean cage the used one being cleaned and disinfected thoroughly before being used again.

Feeding—Guinea pigs like human beings, apes and monkeys require a source of vitamin C (ascorbic acid). Normally they obtain this from greenfood but in winter especially they may not secure enough in this way. The daily requirement of an adult guinea pig is about 2 milligrammes and supplies can be obtained from a chemist's shop.

There are many different methods of feeding guinea pigs. Among cubed or pelleted diets is that known as Diet 18 which is employed also for rabbits. It contains the following parts by weight: wheat feed 15, grass meal 30, decorticated groundnut meal 15, linseed cake 10, barley meal 20, common salt 1 and chalk 1. This is fed together with fresh greenfood to supply vitamin C. For feeding without the use of compressed diets a good plan is to provide a daily concentrate ration of about 1 oz per head of a mixture of 2 parts bran and 1 part crushed oats and to feed in addition ample amounts of cabbage, lettuce or other greenfood, meadow hay of good quality grass and raw vegetables. Although guinea-pigs normally derive moisture from fresh greenfood and may appear to take little or no water for long periods it is a mistake not to provide a fresh supply preferably from water bulbs or from inverted bottles fitted with a stopper and drinking spout. A little dried brewers' yeast makes an excellent addition to the diet while for females (sows) when pregnant or lactating milk is excellent. Dead foliage should be removed from greenfood and soil and dirt cleaned off. Frosted greenfood should be soaked in warm water before it is given to guinea-pigs. Unfortunately hay may be contaminated by wild rodents but it forms an

excellent article of diet. Never allow food residues to remain in the cage.

Breeding—The lactation period of the guinea pig is a short one. The gestation period averages sixty three to seventy five days although variations of fifty eight to seventy two days are known and the young are born in an advanced state with their eyes already open. They can run freely with their mother shortly after birth. They are able to nibble a little food as early as the second day and by the time they are two to three weeks old they are completely independent and are neglected by their mother. A sow will often mate again the day the young are born or shortly after so that a rapid succession of litters often occurs.

Guinea pigs are capable of mating from about fifty five days of age or even younger in certain circumstances which include the provision of a high plane of nutrition. The oestrous cycle averages fifteen to seventeen days although it may vary from thirteen to twenty five days. The actual period during which mating may occur usually lasts only from about six to eleven hours. One boar may run with as many as twenty sows if so desired but in the case of pets it is much more interesting to run a boar with only one sow in which case she need not usually be removed to a separate cage before the young are born. The young guinea pigs should be separated from the older ones shortly after weaning and the sexes separated at four to five weeks of age if they are not to breed prematurely. It is better to wait until the animals are approaching six months of age or so before they are mated for they do not become fully grown and filled out until they are between six and nine months.

Handling—Guinea pigs are timid creatures and should be handled gently. They are best picked up with both hands. If a guinea pig is to be held in order to examine it for any purpose a good method is to place one hand over the animal's shoulders with the fingers and thumb around its neck and to extend its hind limbs with the other hand.

Diseases—The most important infectious disease of guinea pigs is like mouse typhoid caused by organisms of the *Salmonella* group and it may be contracted from wild rodents or from food or bedding contaminated by them. In guinea pigs the disease is known usually as *paratyphoid* (or sometimes as *salmonellosis*) and it may take an acute form causing death within a few days or a more chronic form in which many animals recover to become symptomless carriers of disease. Outwardly healthy they may infect susceptible guinea pigs with which they are placed. Cold or other environmental variations and faulty feeding can help to set off an outbreak, for there are few stocks in which the organisms are not lurking in some latent carriers. *Coccidiosis* is common but is a much less serious threat than in the case of rabbits. It has been set up in infected stocks by feeding inadequate diets and provided that nutrition and hygiene are adequate there is rarely serious trouble from this disease. Infections of the respiratory tract may occur but are uncommon except when there is overcrowding, high humidity or damp bedding. Sometimes organisms of the *Pneumococcus* group cause not only disease of the respiratory tract but also a generalised infection of the serous membranes of the body. When this disease occurs it may produce death without much warning. It is possible that the infection sometimes comes from human beings. The disease known as *pseudotuberculosis* and described under rabbits occurs in guinea-pigs also. Again, environmental conditions and faulty feeding may predispose towards active infection.

With good fortune and sound management trouble from these serious infections may never occur. External parasites should be dealt with promptly by insecticides. Sometimes non-parasitic skin disorders occur when the diet is faulty e.g. too dry or lacking in sufficient fresh greenfood of good quality.

RABBITS

Description—Domesticated varieties of the wild European rabbit (*Oryctolagus cuniculus*) are now kept in many countries. The wild rabbit is believed to have been introduced into Great Britain in the 12th cent. Tame rabbits have been bred for centuries and the breeds and strains produced differ appreciably in size, colour and habits from the common wild form. Some breeds have been specially bred for table purposes while others (e.g. the Angora, Sitka and Argente de Champagne) have been developed for their fur. In addition, many varieties are produced for show purposes by the extensive rabbit fancy. The small hardy Dutch rabbit (usually black and white) is one of the kinds suitable for beginners. Among well known categories are the English, Japanese, Himalayan, Belgian Hare (really a rabbit), Flemish Giant, Beveren, Blue Imperial, Polish, Havana, Lop, Half Lop, Chinchilla and New Zealand White. The Copenhagen rabbit appears to be identical with the New Zealand White. The smaller breeds weigh only 4-6 lb. when fully grown, whereas some specimens of some of the giant breeds attain a weight of 20 lb. or more.

Rabbits and hares were formerly classified with the rodents but are now placed in a separate Order of mammals known as the Lagomorphs. Young rabbits (in contrast to leverets or young hares) are blind and helpless for some time after birth. Tame specimens may live for 4-5 years and individuals have lived for up to 13 years.

Housing—Since rabbits are kept for commercial purposes various systems have been devised including the use of movable ark huts with covered runs that can be moved regularly to fresh ground. If kept indoors rabbits do not need special heating but freedom from draughts, damp, excessive cold and access by wild rodents is most desirable. A garage is regarded as an unsuitable place owing to the susceptibility of rabbits to exhaust or engine fumes. One of the great difficulties of rabbit keeping is coccidiosis, which is a serious disease in rabbits and hares (European hares could never be bred successfully in captivity until means of overcoming coccidiosis were discovered). With young rabbits especially (i.e. those that have left the nest and are able to run about freely) it is a sound principle to move them to a clean floor or fresh ground every two days so as to break the life-cycle of the coccidial parasite. One way of doing this is to have 'back to back' cages or hutches from one to the other of which the rabbits may be transferred easily. The empty cage or hutch may then be cleaned and disinfected thoroughly and allowed to dry out before the rabbits are returned to it. Wood wool makes a suitable bedding material, although the female (doe) will pluck her own fur to line the nest when her litter is due to be born. Wire mesh floors with a tray beneath are convenient but if solid floors are used these should be sprinkled with fresh sawdust daily or every other day. Provided the standard of hygiene can be maintained, cages or hutches and their runs should be large. The absolute minimum is 1 sq. ft. of floor space for each 1 lb. weight of adult rabbit, i.e. if there are two rabbits totalling 12 lb. in weight there must be at least 12 sq. ft. of floor space. If cages or hutches are stacked one on top of the other the lowest should be well clear of the ground and if there is only one hutch this, for convenience and safety from wild rodents, should be 2-3 ft. off the floor.

Feeding—The wild rabbit grazes at dusk and dawn and it is preferable to feed tame rabbits twice daily while pregnant or lactating does and young rabbits benefit from three meals a day. As in the case of guinea pigs, the ration may be thought of as consisting of two parts: a concentrate portion and a portion consisting of greenfood and other succulent material. The concentrate portion consists usually of a mixture of cereal grains or of some other form of mash. Successful mashes of which there are many include (1) a mixture of 4 parts cereal grains and 1 part dairy cake, (2) equal parts of bran, wheatings, flaked maize or barley meal—and fish meal. This

second is useful for breeding. If materials for the mash are in short supply they may in part be replaced by cooked potatoes. An average daily food allowance for a resting (non breeding) adult of medium size would be greenfood (grass, clover, weeds, lettuce etc.) and/or roots 12-18 oz., hay (good quality) 2-3 oz. and concentrates (cereal grain or meal mash) 2 oz. If cooked potatoes are used they should be fed at the rate of 4 parts to each 1 part of cereal that they replace. For a doe nursing her litter a suitable diet would comprise greenfood to appetite, hay (good quality and preferably containing clover or other legume) 2-4 oz., concentrates (preferably with fish meal or some other suitable source of animal protein) 4-6 oz. and common salt at the level of up to 1 per cent of the ration. A mineral mixture is preferable to salt alone. Excessive greenfood, especially in the form of cabbage and other Brassica plants, may cause polyuria, i.e. the passage of excessive quantities of urine. No matter how much fresh greenfood rabbits may have available a supply of fresh water should always be provided. The daily water requirement of the rabbit is quite high and certain bad habits such as urine drinking or even cannibalism may result from an inadequate intake of water. Pots that cannot be overturned or preferably water bulbs or bottles as described for guinea pigs are the most suitable means of providing water.

Diet 18 described under guinea pigs is one of several types of compressed diet successfully employed for rabbits. Fresh greenfood is preferably fed in addition while the water requirement with diets of this kind is considerable.

Breeding—The age of puberty varies with the breed and also with the time of year at which the individual rabbit was born. Rabbits born in spring are usually capable of breeding at a younger age than those born in the autumn. In Great Britain the wild rabbit has a fairly sharply defined main breeding season lasting from January to June but some degree of out of season breeding may take place at almost all other times. Tame rabbits may not breed freely during the winter months especially if environmental conditions are cold. Mating may take place as early as four months of age and although this does not often result in pregnancy it is accompanied by competition and fighting between individuals of the same sex. Males (bucks) and females should therefore be separated at weaning or at least before they are four months old. Fertile matings may occur at from about 55 months of age on wards but it is wise to defer breeding until later—say seven to eight months for most breeds. The female does not ovulate or shed her eggs from the ovary spontaneously as do most domestic mammals but like the cat and ferret does so in response to the act of mating or some other strong stimulus. Even playing between two does may precipitate ovulation in which case a so-called 'phantom pregnancy' (pseudopregnancy) may result the doe that has ovulated appearing pregnant and even developing lactating mammary glands. There is not therefore an obvious regularly recurring oestrus cycle as in the domestic rat, mouse, and guinea-pig, and in summer at least the doe may be ready to mate at almost any time. Observation suggests however that there are fluctuations in the desire to mate. The act of mating in rabbits sometimes causes alarm that all is not well to those that have not hitherto witnessed it; for the buck usually emits a peculiar cry and loses his balance to fall over sideways. It is usually best to separate the buck from the doe before the young are born. The gestation period is usually thirty to thirty-two days. In wild rabbits a high percentage of embryos die and are resorbed and are therefore never born. In some populations it appears that about two-thirds of all rabbits conceived (including about 60 per cent of total litters) are lost before birth in this way. Losses from this cause are probably much less common in domesticated rabbits, especially when the standards of feeding and management are high. Litter size is variable and depends in part on the breed or strain. In some strains mean litter sizes up to eight or nine have been obtained but a mean of four or so is more common. Does that do not prepare the nest or

ear their young properly should not be selected or further breeding. The doe with her new born litter should not be disturbed unduly or she may desert her young which are blind and helpless at birth and are entirely dependent on her for at least three weeks after which they begin to nibble food to supplement the milk that they receive from her. The eyes open at about four teen days. Weaning should be carried out at between six and eight weeks of age by which time the young should be able to fend for them selves completely.

Handling—Rabbits should never be lifted by the ears alone. One good way of lifting them is to grip the ears firmly but gently with one hand and to place the other hand under the rump to take the weight of the rabbit's body. Alternatively one hand may be placed flat under the rabbit's belly but this requires more care and may be a risky procedure with pregnant does. Another convenient way to handle rabbits especially young ones is to lift them by the loose skin over the shoulders. Rabbits can inflict quite nasty scratches with the nails of the hind feet. It is incidentally a good plan to examine the nails of all four feet and to trim them if they are too long. Care should be taken not to cut back as far as the quick i.e. the bluish portion at the base of the nail that contains blood vessels.

Diseases—As already indicated *coccidiosis* is a highly important disease of young rabbits. It may be either of the 'hepatic type' affecting principally the liver or the 'intestinal type' affecting principally the gut. Even in the case of the hepatic type however the coccidial parasites are picked up by mouth and after penetrating the intestinal walls make their way via the blood stream to the liver. Hygienic measures are the best means of preventing the disease (see under *Housing*) but should it break out prompt treatment with certain sulphonamides or other anti-coccidial drugs may prove effective. In certain rabbitries in which coccidiosis is a constant problem protection has been obtained by feeding a dilute solution of one of the soluble sulphonamides in place of drinking water. There are certain types of digestive disturbance that may resemble coccidiosis and one of these the cause of which has not yet been established with certainty is known as *mucoad enteritis*. Some such cases are probably variations of *bloat* (the *blows*) a condition the cause of which is again not fully established although there may in fact be several factors. A rabbit may of course 'bloat' after eating fermentative food but cases of *bloat* can occur independently of this and some may be due to a virus. 'Snuffles' is characterised by a nasal discharge and is not always associated with the same organism. In its milder forms it is not a severe disease, but with the more chronic forms the nasal discharge becomes marked and gives rise to a typical snuffling noise. Severe chronic cases become progressively worse and die of a terminal pneumonia. There is also a severe acute form in which the rabbit dies so rapidly that the condition is sometimes not recognised. Acute cases that are treated in time with certain sulphonamides may respond well but chronic snufflers are difficult to treat and go on spreading the infection and hence are better destroyed. Correct environmental conditions are a great help in preventing this disease. A chronic type of infection is known as *pseudotuberculosis*, which is usually acquired from eating material contaminated by wild rodents or by other infected rabbits. It is caused by quite a different organism from that of true tuberculosis, which is much rarer in rabbits. Clinical cases should be killed and prevention lies in hygienic measures. Infected wounds or skin abscesses may lead to a disease caused by the *necrosis bacillus* (*Pseudomonas aeruginosa*) and known sometimes as *neorodentosis*. It is usually characterised by subcutaneous swellings distributed irregularly over the head and body. Although in the early stages the affected rabbit may remain in apparently good health, the spread of the disease is insidious and usually fatal and in most instances it is kinder and safer to destroy a case before it progresses too far. There are unfortunately

several other infectious conditions occurring in rabbits but all call for expert help in diagnosis and treatment.

Among non infectious conditions *pregnancy toxemia* is not uncommon in does during the very late pregnancy and usually proves fatal within two to three days. It is a metabolic disorder i.e. it is associated with some functional derangement of the endocrine or ductless glands or with the inability to control properly the utilisation of its food. Faulty feeding is probably a contributory cause.

Among external parasites *ringworm* is not common but may be acquired from rodents. Affected rabbits that are to be treated must be isolated. *Ear mange* (known usually as *ear canker*) is common and may be treated by strict attention to hygiene with thorough disinfection of the hut or cage and by dressing with a modern anti-mange preparation. *Body mange* is much less common but far more difficult to treat.

Among internal parasites so called *bladder worms* i.e. the larval stages of two dog tapeworms (*Taenia pisiformis* and *Taenia serialis*) are quite common although rarely fatal. The feeding of grass or other greenstuff to which dogs have had access should be avoided as well as the contamination of the drinking water with dog faeces.

GERBILS

Description—Gerbils also known as jerds and rats and desert rats are members of the sub family *Gerbillinae* of the rodent family *Cricetidae*. There are some fourteen genera comprising some 50 species. The genera *Meriones* and *Gerbillus* are the most widely represented (about 14 and 10 species respectively). Virtually unknown in Britain until the mid 1960s a few species have now been introduced from Asia, Africa and the Middle East initially as laboratory animals.

Gerbils have now become immensely popular pets both in schools and in the home and provided one ensures that a docile species is acquired one has perhaps the ideal pet mammal. They are virtually odourless, easy to handle and to breed and pleasing to watch both in appearance and antics.

Species differ widely in both size and disposition and hence one must take care when acquiring specimens. The Indian gerbil *Tatera indica* is for example large aggressive and virtually untameable. Species recommended include *Gerbillus pyramidum*, *Meriones libicus* and *Meriones unguiculatus* (the Mongolian gerbil). The following advice applies to these species and particularly to the Mongolian gerbil—which is by far the most popular species available in Great Britain and hence the one most likely to be offered.

Housing—Gerbils appear to tolerate a wide range of temperature conditions. Pether has bred several species (though not *M. unguiculatus*) in outdoor conditions in Paris. There is no evidence to suggest that the Mongolian gerbil is less hardy though indoor conditions are advised. Precautions against escape should be exercised since they could become feral and a pest.

Metal cages comprised largely of bars are recommended. Two storey hamper cages are suitable and these enable one to watch the gerbils complex and fascinating behaviour. Provide plenty of hay straw or wood shavings and white paper. The animals shred material to make bedding and 'nests'. Since the animals are virtually odourless as too is their urine and faeces they need cleaning out less frequently than other rodents once per two weeks suffices.

Either a pair of gerbils may be kept or two males with two or three females. It is important however to introduce only young animals from separate litters into the same cage. Adults unused to one another are frequently hostile and aggressive.

Since the animals are burrowers in their natural state they may be kept in a deep container e.g. a large aquarium and supplied with a good depth of peat or a similar material. This method of housing however has the drawback that one sees little of the animals.

Pieces of wood provide a gnawing surface very necessary for most rodents.

Feeding—Virtually nothing is known of the gerbils' natural foods still less their nutritional requirements. One must simply provide a range of foodstuffs from which the animals select what is adequate for their needs. Gerbils will take insects, spiders and meat though they thrive on an entirely vegetarian diet.

Satisfactory foodstuffs include rodent pellets or a coarse seed mixture such as that sold for parrots or for wild birds. Sunflower seeds are taken with avidity as too is germinating grain (i.e. soaked and allowed to grow for a few days to seedling stage). Pieces of raw fruit and vegetable are also consumed.

Water should be provided though the animals drink little particularly if vegetables are available.

Breeding—As indicated under Housing several adults may be run together.

Mating is rarely observed though it is said to occur most usually in the late afternoon. Little is known about the breeding cycle.

The duration of pregnancy is about 25 days and the average litter number about 6. Not infrequently the first litter is small in number and the young may be killed by the parents. Second and subsequent litters are usually reared successfully. Hair develops in 6-10 days and the eyes open at about 3 weeks. Varieties of gerbils are beginning to be reported (Parslow 1970).

Handling—Recently weaned specimens up to some 3 weeks of age require firm cupping in the hands since they are prone to jump with little regard for their own safety.

Regular handling over this age ensures a tame yet ever inquisitive pet. Grasping by the base of the tail is usually necessary to enable one to remove the animal from a cage. Thereafter cupping is to be preferred.

Careless or over enthusiastic handling of a timid individual sometimes produces a fright reaction where the animal lays trembling though otherwise almost inert for a minute or two. However this soon passes.

Diseases—Apart from the vulnerability of the first litter these animals are remarkably healthy. The result of fighting between adults from different cages is the only likely injury encountered apart from occasional skin infection around the nose and lips—possibly due to burrowing activity. This condition responds to a mild antiseptic cream.

Old animals may develop a condition where the eyeball tends to protrude. Neither cause nor cure has been investigated.

Any unwanted or infirm animal may be quickly and painlessly killed by the following procedure: put a little ether (diethyl ether) on a generous pad of cotton wool. Introduce this into a screw cap jar, place the animal in and fix the cap on firmly. Leave for 20 minutes.

LAND TORTOISES

Tortoises are popular pets, but although many are kept with great success in Great Britain the majority of those that are imported each year are never looked after adequately or fail to thrive for other reasons.

Most land tortoises that are imported into Great Britain for sale through dealers are (1) the Spur thighed Mediterranean Land Tortoise (*Testudo graeca*) commonly known as the Moroccan tortoise and sometimes as the Iberian or Algerian or (2) Hermann's Tortoise (*Testudo hermanni*). The second is distributed in Southern France, Southern Italy, the larger islands of the Western Mediterranean, and parts of Yugoslavia, Albania and Greece. There is a species found in Greece the Margined Tortoise (*Testudo marginata*) but while adaptable to life in Great Britain it is more difficult to acquire. The two common species differ in several ways: the Moroccan tortoise having a small bony spur on the back of the thigh. (The upper part of the shell is termed the carapace and the ventral portion the plastron.)

In selecting a tortoise one should ensure that the animal appears healthy. It should be active and withdraw quickly into its shell on being disturbed. Its legs should be firm and not limp and there should be no abnormal discharge from the eyes or nostrils. The shell and limbs should be uninvolved. Females are generally larger and have a shorter tail than the male. The shield above the tail is flat in the former and curved in the male. It is a good idea to obtain a pair or more of tortoises but not more than can be looked after with care. On being purchased they should be washed in tepid water.

Many tortoises are given free range in gardens but this is not advised with all as they eat a wide variety of vegetables and young plants and being wandering animals are liable to get lost if the garden is not completely fenced or walled. They should be provided with as large a pen or run as possible the walls or wire netting of which should be high enough to prevent their climbing over. The practice of tethering tortoises by a hole in the shell should be discouraged. They should always be provided with a box or shelter the cheapest form being a wooden soap box turned on one side and with a sufficiently wide entrance the wood being creosoted and covered with roofing felt. It can be lined with asbestos sheeting if desired and have its floor covered with dry leaves or other bedding material. Some other shelter should also be provided in the run. The tortoises should be bathed during the hot weather. The occasional application of olive oil will keep the shell polished.

Land tortoises must be fed daily and it is important to allow them to build up good reserves to enable them to hibernate through the winter successfully. Suitable foods include lettuce, young cabbage, peas, clover, dandelions, and a wide variety of green plants and ripe sweet fruits. Generally bread and milk should be avoided. For young tortoises especially it is recommended that once weekly or so the food should be sprinkled with powdered cuttlefish bone or better still a small quantity of powdered calcium gluconate or cod liver oil. Fresh water in a shallow tray or even a saucer should always be provided.

One of the most difficult problems in tortoise keeping is hibernation. Some persons avoid allowing their pets to hibernate by transferring them to a warm place such as a heated greenhouse, but this is done they must be kept well fed and their place maintained at a summer temperature. It is imperative to do one thing or the other—the half timid tortoise that is neither hibernating nor kept at summer temperature will die. Moreover a tortoise that is allowed to hibernate must not be disturbed.

Signs of pending hibernation including sluggishness and lowered appetite are usually evident late in September or early in October. Tortoises living in the garden may commence to bury themselves. If this is allowed they must be well covered else they may be killed by the ensuing frost. It is, though more convenient and perhaps provides a greater chance of survival, due to the changeable winter conditions in Britain, to place the animal in a large box, which should be packed with straw, leaves or hay. The box should be stored in a cool but frostproof place such as out building, cellar or attic. It is important not to create conditions that will awaken the tortoise or tempt it to emerge before the following spring. Rats have been known to attack hibernating tortoises and so due precautions should be taken.

On emerging from hibernation the eyes and nostrils are somewhat sealed and should be released by bathing with a 4 per cent boric acid solution and warm water.

Recently imported female tortoises frequently lay eggs, but it is not a common occurrence for pairs to breed freely in Britain. During the early part of the summer the male is sometimes seen butting the shell of the female in a courtship action. If eggs are laid it is unlikely that they will be fertile and less likely that they can be hatched. They have been hatched by placing them on damp sand and storing them in a warm place—a heated greenhouse or airing cupboard. The eggs should not be disturbed or turned once incubation has commenced.

Tortoise ticks are often present on freshly imported specimens and may best be removed by

damping the tick with paraffin or methylated spirits and then removing it gently with tweezers. Round worms are very numerous in tortoises and should they be seen in the fecal matter the remainder may be eliminated by sprinkling up to one grain of powdered santoun on the food once a week for six weeks. Possibly some of the newer safe anthelmintic preparations containing piperazine derivatives may be equally effective. Eye infections are common, and are usually remedied by bathing the eye well with a 4 per cent boric acid solution or warm cod liver oil. Continuous discharge from the nose indicates lung infection and as a primary measure the animal should be kept warm. Bleeding can be stopped by using Friar's Balsam and care should be taken to prevent insects settling on open wounds.

WATER TORTOISES (TERRAPINS)

In Great Britain the tortoises that have become adapted to life in ponds and rivers are usually termed terrapins, the name turtle being applied to marine forms. In the U.S.A. and Canada however not only the marine species but also terrapins and tortoises are all termed turtles.

Several kinds of terrapin are available and capable of thriving in Great Britain. These include several American species, the European Pond Tortoise (*Emys orbicularis*), the Spanish Terrapin (*Emys leprosa*), the Caspian Terrapin (*Emys caspica*) and the Reeves Terrapin (*Chinemys reevesi*) which hails from China and Japan.

The ideal place in which to keep terrapins is a garden pond within an enclosure. The pond should contain an island of dry ground on to which the animals can climb easily. The water should vary in depth and at one point be at least 2 ft deep. Provided that there is a suitable island the boundary walls of the pond can be upright to prevent escape. The final coat of cement should be smooth and mixed with a waterproofing agent. Shade should be available not only on the island but also in some parts of the water. This may be provided by suitable plants.

Terrapins are almost entirely carnivorous although the young of some species may take a little lettuce or other vegetable food. Suitable foods include small pieces of raw meat, raw liver (this should certainly be given from time to time), fish and earthworms. Terrapins prefer to take their food in the water and it is best to feed them individually if there are several to ensure that each receives his proper share.

Water tortoises also hibernate. Some bury themselves in mud or sand at the bottom of their ponds, others will dig themselves into the earth in the island or banks of their pond, while others again may go to sleep in the box that as in the case of land tortoises should preferably be provided for them on part of their land. Should they sleep at the bottom of the pond, it is as well to prevent freezing of the water. One means of doing this is to leave a log or logs floating on the surface. Moving these logs on cold mornings will help to break any ice formed and to prevent total freezing.

AQUARIUM FISH

There are two types of aquaria—the cold water for fish from this and other temperate countries and the heated, for tropical varieties of fish. Apart from the fact that a suitable heating mechanism—usually electric with thermostatic control—has to be maintained for tropical aquaria, the general principles governing the two types are much the same. There is a certain amount of additional initial expense in setting up a heated aquarium—the running costs are not high—but in some respects tropical fish are easier to maintain than many of the cold water varieties.

It should be emphasised at the outset that those who want to keep fish should invest in a proper aquarium and not in a 'goldfish bowl' unless the latter be very large in relation to the fish to be kept. Far too many fish suffer from overcrowding or from lack of sufficient water

surface. In the case of cold freshwater fish such as carp and goldfish (which need quite different conditions from tropical fish) it has been calculated that every 1 in. of body requires 1 sq. ft. of water surface in order to obtain sufficient oxygen for respiration. Thus a fish the body of which (i.e. the length minus the tail fins) is 4 in. will require at least 4 sq. ft. of water surface, i.e. an area of 2 ft. x 2 ft. Two such fish will require twice this area and so on. In *The Right Way to Keep Pet Fish* by R. Dutta (6s.) it is pointed out that a goldfish should normally live for twenty five years in a suitable pond and grow to its full length of over 14 in. There are few indoor aquaria capable of supporting many full grown goldfish in adequate conditions and indeed it is recommended that domestic varieties of goldfish such as shubunkins, fantails, veiltails and orandas which grow more slowly are far better adapted to cold water aquaria. Tropical fish of the varieties kept in aquaria are usually much smaller differ in their oxygen requirements and can be kept in more crowded conditions. Many have an average body length of only about 1½ in. and eighteen such fish may be maintained in a suitably heated tank with an area of water surface of 18 in. x 12 in.

A beginner should not only read good books on the subject (including *Water Life* publications) but also consult experts and his local aquarist or dealer. Whatever aquarium is chosen the conditions should be correct before any fish are introduced. Should fish be suddenly acquired before a proper aquarium has been set up for them, they should be kept in some temporary (but sufficiently capacious) quarters until the aquarium is ready.

The instructions for installing and fitting up an aquarium are usually supplied and should be followed carefully. The sand that is usually placed on the bottom should be thoroughly washed and is best put in a little at a time. Make sure that the inside of the aquarium is thoroughly clean before anything at all is put into it. Ornamental rocks may next be introduced and great care should be taken to ensure that these are of the correct type, unlikely to harm the fish physically or chemically. Water is then added very gently indeed and suitable plants set. In the case of large tanks the planting is best done when the tank is only partly filled with water but in any event the plants themselves should be kept wet all the time or they may quickly shrivel up. In the case of cold water aquaria everything may now be left for a few days—preferably a week or more—to ensure that all is well and to allow certain micro organisms that help form the food of the fish to develop. In the case of heated aquaria it is necessary also to ensure that the thermostat is working correctly and that the temperature is remaining constant or within very narrow limits. Here again it is advisable to wait at least a week before introducing any fish. Should conditions go wrong before or after the fish are introduced it is best to start filling the tank all over again.

Fish should not be overfed although regular feeding is essential. Attention must be paid to the feeding instructions issued with prepared fish foods and to details given by the supplier of live foods. Provided fish are neither over-crowded nor overfed the amount of sediment that accumulates in the tank will not be excessive but it should be siphoned away gently every month, or more often if necessary. Water lost by evaporation should be replaced and in the case of heated tanks especially it is most desirable that the added water be of the same temperature as that already in the tanks.

Certain species of water snail are often placed in aquaria to act as scavengers. It is necessary to ensure that if snails are kept they are of the right type and it is important to consult experts on this matter.

Breeding is an interesting topic, there being both egg laying and viviparous or live bearing fish. The beginner is well advised to learn first how to keep fish in healthy condition in his aquarium before indulging in any planned breeding and he should study the relevant information in books on the subject.

An aeration plant is often recommended on the grounds that it will increase the fish carrying

capacity of the aquarium. This is true up to a point but overcrowding may bring other troubles besides those connected with lack of sufficient oxygen and the golden rule is never to keep too many fish for the size of aquarium in question. Another factor to be remembered is that should the aerator break down it may leave the fish with less oxygen than their proper requirement. It has been recommended that an aerator is best thought of as a stand by to be employed only in emergencies *e.g.* when for some reason extra fish have to be added to a tank already holding all or almost all its proper capacity.

There are unfortunately many diseases of fish and as yet scientific knowledge concerning many of them is far less detailed than it should be. It is clear however that environmental factors are responsible for many deaths or cases of unthriftiness and among the factors concerned may be listed overcrowding overfeeding the provision of a diet that is qualitatively inadequate lack of balance in the aquarium leading to unsuitable conditions dirt too strong light lead paint and noxious substances that may somehow have come into contact with the water (*e.g.* from the hands of the person tending them) or been absorbed from the atmosphere. One must be careful of such things as disinfectants soaps petrol etc. In the case of tropical fish the temperature of the water may be incorrect. Should fish troubles occur therefore it is as well to consider these various possibilities although one should not hesitate to seek professional advice where there appears to be a case of infectious disease. An ailing fish should certainly be removed from the tank (assuming that there are other fish present) and given separate quarters of its own if such a course is feasible.

It is not intended to provide a description of the separate diseases although it may be mentioned that such signs as the appearance of material resembling cotton wool (actual fungal growths) and rotting of the tail or fins are among those that should lead the owner to isolate affected fish and to seek help immediately.

No attempt is made here to describe any of the many different species and varieties of fish suitable for private aquaria. Some of the points

of a fish are shown in the accompanying illustration. Great care must be taken in mixing species *e.g.* hard mouthed and soft mouthed kinds should not be kept together. The temptation to put other species (*e.g.* newts) with aquarium fish must likewise be avoided.

CAGE BIRDS

Very many species and varieties of birds are now maintained successfully in captivity and there exists in Great Britain a large and expanding cage bird fancy that caters for a considerable proportion of the smaller birds adapted to cage or aviary life. The increase in the numbers of budgerigars since the end of the Second World War has been phenomenal and it was estimated during 1957 that the numbers of the species alone in the United Kingdom exceeded 6 millions, the corresponding figure for the U.S.A.—where the popular name is parakeets—being over 18 millions.

The different types and sizes of birds have different requirements and in the space available it is not possible to do more than cover the general principles and to deal briefly with the special characteristics of the management of the more easily maintained species. The beginner is advised to restrict his attention to one of the better

known species *e.g.* canaries or budgerigars and not to attempt to maintain exotic varieties until he has acquired considerable experience.

Most species thrive best in aviaries, which may be indoor outdoor or of the combined indoor-outdoor type. An indoor aviary is usually all wire and portable. The criticism of many such aviaries is that they tend to be high and narrow whereas a fairly large floor space is desirable. They should not be placed in cold or draughty places nor too near a fire. If sited so as to receive much direct sunlight they must have adequate shelter. The wires must be close together especially if smaller species are kept a distance between them of about $\frac{1}{2}$ in being generally suitable. An outdoor aviary—suitable only for some species or at certain times in the case of others—should occupy a sunny position although it too must include shade and must be protected from winds. There ought in fact to be a sheltered portion dry and well protected from the elements. The aviary must be strongly made and safe from all predators including rats and mice. While it is often considered desirable to allow herbage to protrude through the wire mesh floor it is essential that the birds are never in close contact with wild rodents or their droppings. Most birds are highly susceptible to some forms of *salmonellosis* (see under mice and guinea pigs) and can contract them in this way. It is advisable also that the roof of the aviary is solid corrugated asbestos sheeting projecting well clear of the edges of the uprights so as to prevent water and other matter from entering the interior is excellent. The droppings of wild birds may be a potent source of bacterial infection or of internal parasites. To prevent close contact otherwise with wild birds the wire or wire netting walls of the aviary may be double. If an outdoor-indoor aviary is employed there is usually an indoor flight cage separated from the external portion either by a very light hanging door of suitable size through which the birds can easily push their way or by a sliding partition that the owner can operate as required.

SECTION THROUGH CAGE.

If an aviary is out of the question then a suitable cage should be purchased or constructed. The cage need not be ornate—indeed simplicity of design usually facilitates the highly important task of keeping everything clean—but it must be large enough. A cross-section through a breeding cage suitable for canaries and for many other species is shown in the accompanying illustration. Such a cage should measure about 40 in. in length \times 12 in wide \times 18 in. high. It is constructed of wood or some suitable sheeting except for the front which consists of vertical wires with horizontal stays and can be divided into two parts by means of a suitable partition containing a removable section made of wire. By this means the cock and hen canaries can be introduced into the separate sections and develop a courtship before being allowed to be together for actual mating. The cross section indicates the site and size of the removable portion of the partition, and it shows also the removable tray that is such an

excellent fitting for almost any type of cage, and which greatly facilitates cleaning.

Whether an aviary or a cage is employed it is essential to have proper fittings including con-

PERCH

veniently placed drinking troughs, feeding trays, and bird baths and good perches. Much unnecessary discomfort is brought about through the use of unsuitable perches or ones that are incorrectly situated or not sufficiently firm.

NESTING BOX WITH PLAIN WOOD BOTTOM

A suitable type of perch of which there should be several in the cage or aviary is shown in the accompanying illustration and it should be of the appropriate dimensions for the size of bird. In the case of the larger canaries (Norwich and

BIRD BATH

Yorkshire) *eg.* the sectional measurements should be $\frac{1}{2}$ in. \times $\frac{1}{2}$ in., whereas for a smaller canary (Border) they should be $\frac{1}{4}$ in. \times $\frac{1}{4}$ in. The type of perch shown is easy to clean and does not possess awkward corners in which parasites may be harboured. The dimensions of a nesting box, a bird bath and a feeding tray suitable for

canaries are also given in the accompanying illustrations.

While wood is a convenient material for aviary and cage construction it has of course several disadvantages. Out of doors it is best creosoted (lead paint must never be used for places in which birds or other small animals are kept) and indoors it is better lined with hard asbestos sheeting. Metal is suitable—provided that it does not rust or corrode and that the environmental conditions are warm enough.

In all cases a supply of clean fresh water should be available. Strict cleanliness should be observed and professional advice taken immediately if a bird is not thriving.

SOLID TROUGH

CANARIES (*Serinus canarius*)—These are domesticated forms of the race of wild serin found in the Canary Islands and may live up to twenty-five years. Many varieties are known and although most individuals are canary yellow other colours have been developed by fanciers. Many books have been written about the canary although there is still much to be learned concerning its feeding and diseases—as is indeed the case with almost all cage birds. The system of feeding generally recommended is based upon a mixture of 2 or 3 parts of canary seed (which is rich in energy and which is sometimes mixed with a little millet seed) to 1 part of summer rape seed which is high in fat and protein. There seems to have been some difficulty in obtaining suitable rape seed in some areas since the war. The best is German summer rape or Ruben rape. Other seeds are employed as substitutes or for special purposes *eg.* niger is usually added at breeding time and linseed if there is any indication of premature or soft (out of season) moult. Good proprietary seed mixtures are available. A little greenfood should be provided twice weekly and a piece of outleish bone placed between the wires is a suitable source of calcium. Soft bill food (containing boiled egg, dried egg yolk, dried flies and ants' pupae) is also recommended by many breeders while others give chopped egg alone. Others again favour milk especially for young birds.

Breeding is usually started late in March or early in April but not unless the daily shade temperature is at least 50° F. The pairs should be selected earlier than this and transferred to breeding cages with the partition in position. By the middle of February the wire partition may be installed so that the two birds can see one another. A little niger seed is usually added to the diet while finely ground oystershell or eggshell may be sprinkled on the floor. (Otherwise the floor may be covered with washed sand that is not too fine and is free from dust.) When the birds begin to feed one another through the wire they are ready for mating and the partition may be removed. The nest-box can then be inserted and suitable nesting materials *eg.* cow hair and moss placed in the cage. The incubation period is thirteen to fourteen days. After the eggs are laid some owners prefer to separate the cock and the hen but allow him to rejoin her after the young are all about eight to nine days old and have opened their eyes. If it is desired that all the chicks be hatched together then one can remove the first three eggs that are laid—usually one egg is laid daily—and keep them in a box at room temperature substituting dummy eggs for them in the nest-box. On the afternoon of the third day of laying they are returned to the nest-box in place of the dummies.

When the young chicks are able to feed for them selves they should be provided with special food such as egg and bread crumbs and a little cracked canary seed. If the cock bird interferes with them, or causes the hen to neglect them, he must be returned to his own section. Usually however all goes well and the hen will go to the nest again when the first chicks are almost sixteen days old. Some three or four broods may be raised in a season.

WAXBILLS FINCHES AND OTHER SEED EATERS—The canary is of course a finch but most of the other foreign finches are considered by dealers and writers together with other types of seed-eating birds. Well over 30 species of *Aradats Buntings*, *Mammals Gardinals*, *Whydahs Weavers* and *Finches* of various descriptions have been maintained successfully in captivity in Great Britain. One of the most popular is the *Zebra finch* (*Taeniopygia castanotis*) from Australia, which has bred so successfully in this country that supplies no longer depend upon fresh importations and which is already appearing in several varieties. The native bird and many of its descendants are grey and white with red beaks. The male bird has orange cheek patches and orange flanks with white markings. The throat has black barring on a white background and indeed the characteristic markings of the male have been the subject of interesting behaviour studies. The female lacks these special markings. The species is hardy and is capable of living in outdoor aviaries all the year round so long as it has shelter from draughts or strong winds and adequate facilities for roosting. If provided with nest boxes the birds will attempt—often successfully—to breed all the year round so to avoid overbreeding it is better to remove these boxes in winter. A mixture of millet and canary seed forms the basis of their diet, which should be supplemented with fresh greenfood, millet sprays, fine grit and cuttlebone—and of course fresh water should be available. Another bird suitable for the relatively uninitiated bird keeper is the *Bengalese* (a domestic variety of *Munia strata*). It seems that these birds are the result of careful breeding by the Japanese and may be regarded as fertile hybrids. Three main forms, the Chocolate and White, the Fawn and White, and the White have been developed. These birds will thrive in cages or in aviaries. As in the case of Zebra Finches they will attempt to breed all the year round if provided with nest boxes. *Bengalese* are sociable birds, sometimes known in the U.S.A. as Society Finches. They appear to require less additional food than most species, thriving on a mixture of canary and millet seed together with grit, cuttlebone and an occasional millet spray or item of greenstuff.

For details of these birds, and of the many others from which a selection may be made works of reference should be consulted. Three very useful books all published by Cage Birds London, are *Foreign Bird Keeping* by Edward J. Boosey (63s.), *Foreign Birds for Beginners* by D. H. S. Rasdon (10s. 6d.) and *Foreign Birds for Garden Aviaries* by Alec Brooksbank (10s. 6d.).

BUDGERIGARS—The increase in the popularity of this bird has been phenomenal although to those who have experience of other birds as pets the reasons are soon fairly obvious. Apart from the capacity to talk shown by many birds—especially males—kept alone and trained, there is a liveliness, almost a cheekiness and an apparent like of human companionship. The wild green budgerigar (*Melospittacus undulatus*) exists in large numbers in the grassland and desert shrub regions of Australia. The usual colour is grass green—it is frequently known as the Grass Parakeet—with a yellow mask, with three black spots on either side. As a result of intensive breeding a considerable number of colour varieties has been produced, and the genetics of colour are a constant source of interest to budgerigar breeders. A vast budgerigar fancy has been built up in the United Kingdom, the U.S.A. and other countries, and World Budgerigar Congresses are held every few years. Budgerigars will thrive in outdoor aviaries all the year round but the vast majority

are kept as indoor pets in cages or small aviaries. The cages can be similar to those used for canaries and care should be taken that the perches are of the correct diameter. If nest boxes are put up and the environmental conditions are suitable budgerigars suitably paired will breed at almost any time of the year. It is customary however to restrict breeding to the spring summer and early autumn. Overbreeding may lead to difficulties including the production of runts or French moult. The sexes may normally be distinguished at any rate in mature individuals by the colour of the cere at the base of the beak which is blue in males and brown in females. Males may lose their colour if not in good condition and for other reasons.

There are now many proprietary seed mixtures but some owners prefer to make up their own mixtures of millet (usually mixing small yellow and large white varieties) and canary seed. Millet sprays, fresh greenfood, good grit and cuttlebone are all desirable and it is important that the correct size and consistency of grit be chosen. Variety in extras to the basal seeds diet is probably important for the captive bird has not the same opportunity, as its wild ancestors for ranging widely for possibly important trace items of food. Breeding birds secrete a milk comparable with the crop milk of pigeons and some other birds and this is of importance in the early feeding of the young.

Most healthy budgerigars seem to live to the age of 3-7 years or more and considerably greater ages have been attained in captivity.

Such is the development of the budgerigar fancy that most equipment as well as food can be obtained ready for use. The playful habits of budgerigars have led to their being given table tennis balls or a variety of small toys to play with while some forms of food are supplied as budgerigar bells or otherwise in special shapes that seem to amuse the birds as they take the constituent seed from them.

The study of budgerigar diseases is in its infancy but already some important facts have become realised. *French moult* is certainly reproducible by overbreeding and may be linked with deficiencies in the ability of the parent birds to feed their young—or to hand over to them at the time of laying sufficient nutritional reserves to carry them through hatching and parental feeding until the time that they can fend for themselves. A deficiency in the milk has been shown in some cases and may be generally true. Large chicks can be produced by killing off or removing all but a single member of the clutch, and allowing the parents to deal with it alone.

A milk infestation, due to *Cnemidocoptes pilae* may give rise to *Scaly face*, *Scaly back* or *Scaly leg* which veterinary treatment is now available. Another condition known as *Brown hypertrophy of the cere* is characterised by thickening and darkening of the surface of the cere. In the early stages it is sometimes thought that the bird is changing its sex. There is no known successful treatment at the time of writing and if the overgrowth is cut away it will only reform. There are various disturbances of the digestive tract and some of these may be associated with inability to stand properly.

There are many treatises on the budgerigar. A useful little work is *Budgerigar Guide* by Cassa Feyerbrand (Fond du Lac Wisconsin All Pets Magazine).

LOVEBIRDS AND PARROTTLETS are also members of the parrot family and while they are unlikely to equal the budgerigar in popularity they are nevertheless interesting birds that are being kept in increasing numbers as pets. Lovebirds of the genus *Agapornis* are African in origin, and some six species are commonly kept in captivity. Parrotlets derive from South America, the commonest species being the Guiana Parrotlet *Forpus passerinus*. Both types of bird are relatively simple to maintain in aviaries or large cages, and their basal diet (which should be supplemented widely) is a mixture of millet and canary seed. They are hardy and vigorous creatures many details of which are to be found in condensed form in *Lovebirds and Parrotlets* by C. P. Linke (London Cage Birds 8s. 6d.).
